MEDICAL- SURGICAL NURSING

Patient-Centered Collaborative Care

7th
Edition

ELSEVIER

<http://evolve.elsevier.com>

CONTENTS

UNIT I FOUNDATIONS FOR MEDICAL-SURGICAL NURSING

- 1 Introduction to Medical-Surgical Nursing, 1
- 2 Introduction to Complementary and Alternative Therapies, 8
- 3 Common Health Problems of Older Adults, 15
- 4 Cultural Aspects of Health and Illness, 30
- 5 Pain: The Fifth Vital Sign, 39
- 6 Genetic Concepts for Medical-Surgical Nursing, 64
- 7 Evidence-Based Practice in Medical-Surgical Nursing, 79
- 8 Rehabilitation Concepts for Chronic and Disabling Health Problems, 89
- 9 End-of-Life Care, 106

UNIT II CONCEPTS OF EMERGENCY CARE AND DISASTER PREPAREDNESS

- 10 Concepts of Emergency and Trauma Nursing, 121
- 11 Care of Patients with Common Environmental Emergencies, 136
- 12 Concepts of Emergency and Disaster Preparedness, 155

UNIT III MANAGEMENT OF PATIENTS WITH FLUID, ELECTROLYTE, AND ACID-BASE IMBALANCES

- 13 Assessment and Care of Patients with Fluid and Electrolyte Imbalances, 165
- 14 Assessment and Care of Patients with Acid-Base Imbalances, 196
- 15 Infusion Therapy, 210

UNIT IV MANAGEMENT OF PERIOPERATIVE PATIENTS

- 16 Care of Preoperative Patients, 239
- 17 Care of Intraoperative Patients, 263
- 18 Care of Postoperative Patients, 284

CONCEPT OVERVIEW: PROTECTION

UNIT V PROBLEMS OF PROTECTION: MANAGEMENT OF PATIENTS WITH PROBLEMS OF THE IMMUNE SYSTEM

- 19 Inflammation and the Immune Response, 302
- 20 Care of Patients with Arthritis and Other Connective Tissue Diseases, 318
- 21 Care of Patients with HIV Disease and Other Immune Deficiencies, 357
- 22 Care of Patients with Immune Function Excess: Hypersensitivity (Allergy) and Autoimmunity, 383
- 23 Cancer Development, 396

- 24 Care of Patients with Cancer, 408
- 25 Care of Patients with Infection, 434

UNIT VI PROBLEMS OF PROTECTION: MANAGEMENT OF PATIENTS WITH PROBLEMS OF THE SKIN, HAIR, AND NAILS

- 26 Assessment of the Skin, Hair, and Nails, 451
- 27 Care of Patients with Skin Problems, 470
- 28 Care of Patients with Burns, 511

CONCEPT OVERVIEW: OXYGENATION AND TISSUE PERFUSION

UNIT VII PROBLEMS OF OXYGENATION: MANAGEMENT OF PATIENTS WITH PROBLEMS OF THE RESPIRATORY TRACT

- 29 Assessment of the Respiratory System, 543
- 30 Care of Patients Requiring Oxygen Therapy or Tracheostomy, 562
- 31 Care of Patients with Noninfectious Upper Respiratory Problems, 580
- 32 Care of Patients with Noninfectious Lower Respiratory Problems, 600
- 33 Care of Patients with Infectious Respiratory Problems, 640
- 34 Care of Critically Ill Patients with Respiratory Problems, 662

UNIT VIII PROBLEMS OF CARDIAC OUTPUT AND TISSUE PERFUSION: MANAGEMENT OF PATIENTS WITH PROBLEMS OF THE CARDIOVASCULAR SYSTEM

- 35 Assessment of the Cardiovascular System, 686
- 36 Care of Patients with Dysrhythmias, 711
- 37 Care of Patients with Cardiac Problems, 744
- 38 Care of Patients with Vascular Problems, 772
- 39 Care of Patients with Shock, 808
- 40 Care of Patients with Acute Coronary Syndromes, 828

UNIT IX PROBLEMS OF TISSUE PERFUSION: MANAGEMENT OF PATIENTS WITH PROBLEMS OF THE HEMATOLOGIC SYSTEM

- 41 Assessment of the Hematologic System, 855
- 42 Care of Patients with Hematologic Problems, 869

MEDICAL- SURGICAL NURSING

Patient-Centered Collaborative Care

YOU'VE JUST PURCHASED MORE THAN A TEXTBOOK

ACTIVATE THE COMPLETE LEARNING EXPERIENCE
THAT COMES WITH YOUR BOOK BY REGISTERING AT
<http://evolve.elsevier.com/lggy/>

Once you register, you will have access to your
FREE STUDY TOOLS:

- **Review Questions for the NCLEX® Examination**
Interactive NCLEX® Examination–style review questions, including prioritization and delegation and pharmacology questions, are divided by chapter to help you review and apply important content and study for the NCLEX® Examination.
- **Answer Guidelines for Decision-Making Challenges and NCLEX® Examination Challenges**
The Decision-Making Challenges and NCLEX Examination Challenges that appear throughout the text provide a safe and effective means of practicing the clinical reasoning and clinical decision-making skills you will need in the clinical setting. Suggested Answer Guidelines are provided on Evolve for these exercises, allowing you to gauge your mastery of essential content and your readiness for clinical practice.
- **Printable Expanded Key Points**
Downloadable, printable files provide an innovative way to review essential chapter content and study for exams. The Key Points include expanded point-by-point highlights from each chapter.
- **Interactive Case Studies**
Interactive Case Studies, including documentation questions, offer an opportunity to apply important concepts of nursing care to realistic medical-surgical scenarios. Compare your answers with an expert's response at the click of a button.
- **Additional Resources**
Audio Glossary, Concept Map Creator, Fluids & Electrolytes Tutorial, Health Assessment Image Collection, Video Clips, Audio Clips, Animations, Tips for Student Success, and more!

In order to make safe and effective judgments using NANDA-I nursing diagnoses it is essential that nurses refer to the definitions and defining characteristics of the diagnoses listed in the work."

Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

The first edition of this textbook, entitled *Medical-Surgical Nursing: A Nursing Process Approach*, received widespread acclaim in the early 1990s. The following five editions built on that achievement and further solidified the book's position as a major trendsetter for the practice of adult health nursing. Now in its seventh edition, "Iggy" charts an essential course for the future of adult nursing practice—a course reflected in its current title: *Medical-Surgical Nursing: Patient-Centered Collaborative Care*. The focus of this new edition continues to be to help students learn how to provide safe, quality care that is patient-centered, evidence-based, and collaborative.

The book's subtitle was carefully chosen to emphasize the nurse's role in providing patient care in collaboration with members of the interdisciplinary team in both acute care and community-based settings. The Institute of Medicine (IOM), The Joint Commission, the National Quality Forum, and other health care organizations have called for all health professionals to coordinate and deliver patient care as a collaborative care team. In addition, the 2010 IOM *Future of Nursing* report states that nurses need to have requisite competencies, including research and evidence-based practice, and teamwork and collaboration to deliver safe, high-quality care in specific content areas such as community health and geriatrics.

Patient safety is also emphasized in this edition with references to The Joint Commission's National Patient Safety Goals initiative (http://www.jointcommission.org/standards_information/npsgs.aspx). A new feature for the seventh edition, Nursing Safety Priority boxes, enables students to immediately identify the most important care needed for patients with specific health problems. These highlighted features are further classified as Action Alerts, Drug Alerts, or Critical Rescue boxes.

KEY THEMES FOR THE 7TH EDITION

The seventh edition continues to use the term "patient" instead of "client" throughout. Although the use of these terms remains a subject of discussion among nursing educators, we have not defined the patient as a dependent person. Rather, the patient can be an individual, a family, or a group, all of whom have rights that are respected in a mutually trusting nurse-patient relationship. Most health care agencies and professional organizations use "patient" in their practice and publications. In addition, many nursing organizations support the term.

As in the sixth edition, the seventh edition relates the focus of critical thinking to an emphasis on nursing judgment to make timely and appropriate clinical decisions. To help achieve that focus, all new case-based Decision-Making Challenges based on the Quality and Safety Education (QSEN) core competencies have been integrated throughout the text. These exercises provide clinical situations in which students can practice on-the-spot decision making to help prepare them for the fast-paced world of medical-surgical nursing and become competent nurses. Suggested answer guidelines

for these Decision-Making Challenges are provided on the book's Evolve website (<http://evolve.elsevier.com/Iggy/>).

In addition to this key theme of clinical decision-making, the seventh edition also emphasizes "readiness"—readiness for the NCLEX® Examination, readiness for major emergencies such as we saw in the aftermath of the events of 9/11 and recent natural disasters, readiness for safe drug administration, and readiness for the new world of genetics and genomics that is unfolding before us. An increased number of NCLEX® Examination Challenges, now including some with alternate-format items, are interspersed throughout the text to allow students the opportunity for practice in test-taking.

As the nursing shortage becomes more acute, it is more critical than ever that students be ready to pass the licensure exam on the first try. To help both students and faculty achieve that outcome, chapter-opening Learning Outcomes are consistent with the objectives outlined in the detailed NCLEX-RN® Test Plan. The seventh edition also continues to include an innovative end-of-chapter feature called "Get Ready for the NCLEX® Examination!" This unique and popular learning aid consists of a list of Key Points *organized by Client Needs Category* as found in the NCLEX-RN® Test Plan.

To further help students connect previously learned concepts with new information in the text, six Concept Overviews introduce groups of content units. These unique features review basic concepts learned in nursing fundamentals courses—such as oxygenation and protection—to help students make connections between fundamental concepts and patient care for medical-surgical conditions. At the end of each body system chapter, Nursing Concept Reviews apply these same concepts to the health problems presented in the chapter. Dr. Christine Tanner's clinical judgment framework is used to help students apply these concepts (Tanner, 2006). The components of this model include that clinical nurses use nursing judgment to provide quality care by:

- Noticing
- Interpreting
- Responding
- Reflecting

This seventh edition includes a new chapter—**Chapter 7: Evidence-Based Practice in Medical-Surgical Nursing**—written by evidence-based practice (EBP) experts Dr. Rona F. Levin and Fay Wright. This chapter discusses the importance of EBP and incorporating it into nursing care. This chapter, along with the Evidence-Based Practice boxes throughout the book, offers a solid foundation in this increasingly important aspect of nursing practice emphasized by the QSEN initiative.

Additional themes carried over from the previous edition are an emphasis on women's health issues, genetic/genomic considerations, cultural awareness, complementary and alternative therapies, and the special needs of older adults. In addition, concepts of case management and community-based care are interwoven throughout to help students identify the role of the nurse in providing continuing patient care.

CLINICAL CURRENCY AND ACCURACY

To ensure the book's currency and accuracy, we listened to students and faculty who have used the previous editions, focusing on their impressions of and experiences with the book. We reviewed documents crafted by a variety of health care organizations, including the Institute of Medicine (IOM), The Joint Commission (TJC), and the Institute for Healthcare Improvement (IHI). Recent nursing education publications were also examined, such as those authored by the National League for Nursing (NLN), the American Association of Colleges of Nursing (AACN), and Dr. Patricia Benner and her colleagues in their book *Educating Nurses: A Call for Radical Transformation* (2010). A thorough nursing education literature search of best current evidence helped us validate best practices and national health care trends to help shape the focus of the seventh edition.

We also commissioned in-depth reviews of every chapter by clinicians and instructors from across the United States and used their reviews to guide us in revising the chapters into their final form. A well-respected interventional radiologist ensured the accuracy of selected diagnostic testing procedures and associated patient care.

The results of these efforts are reflected in the seventh edition's:

- Strong, consistent focus on NCLEX-RN® Examination preparation, clinical decision making, patient-centered collaborative care, pathophysiology, drug therapy, evidence-based clinical practice, and community-based care
- Foundation of relevant research and best practice guidelines
- Emphasis on the critical “need to know” information that beginning nurses must master to provide safe patient care

Best Practice for Patient Safety & Quality Care charts help highlight the most important nursing care. Our Evidence-Based Practice boxes include a Commentary section, as well as a rating of the level of evidence based on a well-respected scale outlined in [Chapter 7](#).

With today's knowledge explosion, it is easy for a book to become larger with each new edition. However, today's nursing students have a limited time to absorb and begin to apply the information essential for medical-surgical nursing care. Therefore in this seventh edition we eliminated some of the content found in previous foundation courses or other specialty textbooks. We limited our discussions to how these concepts are used in adult nursing and focused on content that was “need to know” for safe, quality nursing practice.

OUTSTANDING READABILITY

Today's students need to be able to read information once and understand it; they do not have time to repeatedly read the same information. To achieve this level of readability, the text has a more direct-address style (wherever appropriate) that speaks directly to the reader, and sentences are as short as possible without sacrificing essential content.

Reading level is highly influenced by the length of sentences and the length of words. Although we can control the length of the sentences, medical terms are often 4 to 5 syllables long and tend to skew a chapter's reading level.

Nevertheless, the result of our efforts is a med-surg text of consistently outstanding readability. The average reading level is 10th to 11th grade. It is important to note that reducing the reading level of this edition did not reduce the quality or depth of content that students need to know. Instead, the content is clear, focused, and accessible.

EASE OF ACCESS

To make the text as easy to use as possible, we have maintained the previous editions' approach of smaller chapters of more uniform length. Although we eliminated some of the foundational content in the first unit of the last edition and added one new chapter, the seventh edition remains 76 chapters long.

We also have maintained the unit structure of previous editions, with vital body systems (cardiovascular, respiratory, and neurologic) appearing earlier in the book. In these three units we continue to provide complex care content in separate chapters that discuss managing critically ill patients with coronary artery disease, respiratory health problems, and neurologic health problems.

To help break up long blocks of text and also to highlight key information, we continue to include numerous headings, bulleted lists, tables, charts, and in-text highlights. Key Terms are in boldface color type and are defined in the text to foster the learning of need-to-know vocabulary. A glossary is located in the back of the book. Chapter bibliographies have been moved to the back of the book to save space in chapters for need-to-know content. These current bibliographic resources include research articles, nationally accepted clinical guidelines, and other sources of evidence when available for each chapter. Classic sources from before 2008 are noted with an asterisk (*).

A PATIENT-CENTERED COLLABORATIVE CARE APPROACH

As in all previous editions, we take a collaborative care approach to patient care. We believe that in the real world of health care, nurses, patients, and other health care providers (including physicians, advanced-practice nurses, and physician's assistants) *share* responsibility for the management of patient problems. Thus we present patient care in a collaborative care framework. In this framework we make no *artificial* distinctions between medical treatment and nursing care. Instead, under each Patient-Centered Collaborative Care heading we discuss how the nurse coordinates care and interacts with members of the health care team as appropriate for the patient's health problems, including health promotion and illness prevention.

This edition includes newly redesigned patient-centered Concept Maps that underscore this collaborative care approach. Each Concept Map contains a case scenario. It then shows how a selected complex health problem is addressed. Each Concept Map spells out the steps of the nursing process and related concepts to illustrate the relationships among disease processes, priority patient problems, collaborative management, and more.

Although our approach is collaborative, the text is first and foremost a *nursing* text. We therefore use a nursing process approach as a tool to organize discussions of patient health problems and their management. Discussions of *major* health

problems follow a full nursing process format using this structure:

- [Health problem]
 - Pathophysiology
 - Etiology (and Genetic Risk when appropriate)
 - Incidence/Prevalence
 - Health Promotion and Maintenance (when appropriate)
 - Patient-Centered Collaborative Care
 - Assessment
 - Analysis
 - Planning and Implementation
 - [Collaborative Intervention Statement (based on priority patient problems)]
 - Planning: Expected Outcomes
 - Interventions
 - Community-Based Care
 - Home Care Management
 - Teaching for Self-Management
 - Health Care Resources
 - Evaluation: Outcomes

The Analysis sections list the priority patient problems (collaborative problems and nursing diagnoses) associated with major medical disorders. This seventh edition uses official NANDA-I nursing diagnosis language where it applies; however, most health care agencies prefer to identify collaborative patient problems or needs as the basis for the interdisciplinary plan of care rather than being restricted to NANDA-I language, which addresses primarily nursing-oriented patient problems. With its more flexible interweaving of NANDA-I diagnoses and collaborative patient problems or needs, the seventh edition more closely aligns with the language of actual clinical practice. The nursing diagnoses used in this edition are the 2012-2014 NANDA-I diagnoses—the most recently approved diagnoses at the time of publication of this edition. Health Promotion and Maintenance sections are found in selected discussions.

Discussions of less common or less complex disorders, although not given this complete subhead structure, nonetheless follow the same basic format: a discussion of the problem itself (including pertinent information on pathophysiology) followed by a section on collaborative care of patients with the disorder. To demonstrate our commitment to providing the content foundational to nursing education and consistent with the recommendations of Benner and colleagues through the Carnegie Foundation for the Future of Nursing Education, we highlight throughout this edition essential pathophysiologic concepts that are key to understanding the basis for collaborative management.

Integral to this collaborative care approach is a clear delineation of just who is responsible for what. When a responsibility is primarily the nurse's, the text says so. When a decision must be made jointly by the patient, nurse, physician, and physical therapist, for example, this is clearly stated. When different health care practitioners in different care settings might be involved in the patient's care, this is stated.

ORGANIZATION

The 76 chapters of *Medical-Surgical Nursing: Patient-Centered Collaborative Care* are grouped into 16 units. Unit 1, Foundations for Medical-Surgical Nursing, lays the

foundation for the health care concepts incorporated throughout the text. Unit 2 consists of three chapters on concepts of emergency and trauma care and disaster preparedness.

Unit 3 consists of three chapters on the management of patients with fluid, electrolyte, and acid-base imbalances. Chapters 13 and 14 review key assessments and related patient care in a clear, concise discussion. The chapter on infusion therapy (Chapter 15) is supplemented with an online Fluids & Electrolytes Tutorial on the companion Evolve website.

Unit 4 presents the perioperative nursing content that medical-surgical nurses need to know. This content provides a solid foundation to help the student better understand the collaborative care required for the surgical patient.

Unit 5 provides core content on health problems related to immune system function. This content includes normal inflammation and the immune response, altered cell growth and cancer development, and interventions for patients with connective tissue disease, HIV infection, and other immunologic disorders, cancers, and infections.

The remaining 11 units, subdivided and introduced by the six Concept Overviews, cover medical-surgical content by body system. Each of these units begins with an Assessment chapter and continues with one or more Nursing Care chapters for patients with selected health problems in that body system. This framework is familiar to students who learn the body systems in preclinical foundational science courses such as anatomy and physiology.

MULTINATIONAL, MULTICULTURAL, MULTIGENERATIONAL FOCUS

To reflect the increasing diversity of our society, *Medical-Surgical Nursing: Patient-Centered Collaborative Care* takes a multinational, multicultural, and multigenerational focus. Addressing the needs of both U.S. and Canadian readers, we have included examples of trade names of drugs available in the United States and in Canada. Drugs that are available only in Canada are designated with a 🍁 symbol. When appropriate, we identify specific Canadian health care resources, including their websites.

To help nurses provide quality care for patients whose cultural background may differ from their own, numerous Cultural Awareness boxes highlight important aspects of culturally competent care throughout the text. A revised and expanded cultural health chapter (Chapter 4) includes specific information about lesbian, gay, bisexual, and transgender (LGBT) health and health care, as well as special needs associated with homelessness and dwarfism. Located in an appendix is an innovative Communication Quick Reference for Spanish-Speaking Patients. This Quick Reference helps ensure clear communication between native English speakers and the rapidly growing population who speak Spanish as a first language.

Increases in life expectancy and the “graying” of the baby-boom generation add up to a steadily increasing older adult population. To help equip nurses for this challenge, the seventh edition continues to provide thorough coverage of the care of older adults. Chapter 3 offers content on the role of the nurse and health care team in promoting health for older adults in the community. It also provides coverage of common health problems that older adults may have in the

health care setting, such as falls and inadequate nutrition. The text includes many Nursing Focus on the Older Adult charts. Laboratory values and drug dosages typical for older patients are also included throughout the book. Charts specifying normal physiologic changes to expect in the older population are found in each Assessment chapter. In addition, Considerations for Older Adults boxes are included throughout the text to emphasize key points to consider when caring for these patients.

Also appearing throughout the text are Women's Health Considerations boxes, which address topics of concern to women and their health care providers. These in-text highlights alert the reader to gender-related differences in assessment parameters and in the incidence, severity, and treatment of common health problems.

ADDITIONAL LEARNING AIDS

As in previous editions, the seventh edition continues to include a rich array of learning aids geared toward adult learners to help students quickly identify and understand key information and to serve as study aids.

- Written in “patient-friendly” language, Patient and Family Education: Preparing for Self-Management charts provide the types of instructions that nurses must learn to provide to patients and their families to help them cope with life changes caused by illness.
- Laboratory Profile charts summarize important information on laboratory tests commonly used to evaluate health problems. Information typically includes normal ranges of laboratory values (including differences for older adults, when appropriate) and the possible significance of abnormal findings.
- Common Examples of Drug Therapy charts summarize important information about commonly used drugs. Most charts include both U.S. and Canadian trade names for typically used drugs, usual dosages (including dosages for older patients, as appropriate), and nursing interventions with rationales.
- Key Features charts highlight the clinical manifestations of important health problems based on pathophysiologic concepts.
- Evidence-Based Practice boxes, provided in nearly every chapter, give synopses of recent nursing research articles and other scientific articles applicable to nursing. Each box provides a brief summary of the research, its level of evidence (LOE), and a brief commentary with implications for nursing practice and future research. The purpose of this feature is to help students identify the strengths and weaknesses of the research and to see how research guides nursing practice.
- As in the previous editions, Home Care Assessment charts serve as a convenient summary of essential assessment points for patients who need follow-up home health nursing care.
- Assessment Using Gordon's Functional Health Patterns charts provide a convenient one-stop list of questions to ask patients about the impact of health conditions on everyday function.
- New to this edition, subtypes of Decision-Making Challenges emphasize the six QSEN core competencies:

Patient-Centered Care, Teamwork and Collaboration, Evidence-Based Practice, Quality Improvement, Safety, and Informatics.

AN INTEGRATED MULTIMEDIA RESOURCE BASED ON PROVEN STRATEGIES FOR STUDENT ENGAGEMENT AND LEARNING

Medical-Surgical Nursing: Patient-Centered Collaborative Care, 7th edition, is the centerpiece of a comprehensive package of electronic and print learning resources that break new ground in the application of proven strategies for student engagement, learning, and evidence-based educational practice. This integrated multimedia resource actively engages the student in problem solving and practicing clinical decision-making skills.

Resources for Instructors

For the convenience of faculty, all Instructor Resources are available on a streamlined, secure instructor area of the Evolve website (<http://evolve.elsevier.com/Iggy/>). Included among these Instructor Resources are the exciting new *TEACH for Nurses* Lesson Plans. These Lesson Plans focus on the most important content from each chapter and provide innovative strategies for student engagement and learning. Lesson Plans are provided for each chapter and are categorized into several parts:

- Objectives
- Teaching Focus
- Key Terms
- Nursing Curriculum Standards
 - QSEN
 - Concepts
 - BSN Essentials
- Student Chapter Resources
- Instructor Chapter Resources
- Teaching Strategies

Additional Instructor Resources provided on the Evolve website include:

- A completely revised, updated, high-quality Test Bank consisting of 2260 items, both traditional multiple-choice and NCLEX-RN® “alternate” item types. Each question is coded for correct answer, rationale, cognitive level, NCLEX Integrated Process, and NCLEX Client Needs Category. Page references are provided for Remembering (Knowledge)- and Understanding (Comprehension)-level questions. (Questions at the Applying [Application] and above cognitive level require the student to draw on understanding of multiple or broader concepts not limited to a single textbook page, so page cross references are not provided for these higher-level critical thinking questions.) The Test Bank is provided in ExamView, ParTest, and rich-text formats.
- An electronic Image Collection containing all images from the book (approximately 630 images), delivered in a format that makes incorporation into lectures, presentations, and online courses easier than ever.
- PowerPoint Presentations—a collection of over 2000 slides corresponding to each chapter in the text and highlighting key content with integrated images and

Unfolding Case Studies. Audience Response System Questions (three discussion-oriented questions per chapter for use with iClicker and other audience response systems) are folded into these slide presentations.

- Guest Lectures—Seven ready-to-use narrated PowerPoint presentations by Dr. Workman covering topics with which both students and faculty tend to struggle.
- Faculty Development Videos—two videos by Donna Ignatavicius addressing (1) the implications of changes in the NCLEX-RN® Examination for faculty and (2) curriculum transformation.

Also available for adoption and separate purchase, Simulation Learning System (SLS) helps faculty make the best use of high-fidelity patient simulators.

Resources for Students

Resources for students include a revised and updated Clinical Decision-Making Study Guide, a Clinical Companion, a Virtual Clinical Excursions workbook/CD-ROM, and Evolve Learning Resources.

The *Clinical Decision-Making Study Guide* has been revised and updated and features a continued emphasis on clinical decision making, priorities of delegation, management of care, and pharmacology. The use of Case Studies is expanded in this edition, and documentation questions have been added to most chapters to provide practice with this important aspect of the evaluation step of the nursing process.

The pocket-sized *Clinical Companion* is a handy clinical resource that retains a popular alphabetical organization and streamlined format. It now includes new “Critical Rescue,” “Drug Alert,” and “Action Alert” highlights throughout based on the Nursing Safety Priority features in the textbook. National Patient Safety Goals highlights underscore the importance of observing vital patient safety standards. This “pocket-sized Iggy” has been tailored to the special needs of students preparing for clinicals and clinical practice.

The *Virtual Clinical Excursions 3.0* workbook/CD-ROM package, featuring an updated and easy-to-navigate “virtual” clinical setting, will once again be available for the seventh edition. This unique learning tool guides students through a

virtual clinical environment and helps them “learn by doing” in the safety of a “virtual” hospital. The clinical simulations and workbook represent the next generation of research-based learning tools to promote critical thinking and meaningful learning.

Also available for students is a dynamic collection of Evolve Student Resources, available at <http://evolve.elsevier.com/Iggy/>. The Evolve Student Resources —organized by student learning needs—include the following:

- Review Questions for the NCLEX® Examination
- Answer Guidelines for NCLEX® Examination and Decision-Making Challenges
- Interactive Case Studies
- Concept Maps (digital versions of the 12 Concept Maps from the text)
- Concept Map Creator (a handy tool for creating customized Concept Maps)
- Fluid & Electrolyte Tutorial (a complete self-paced tutorial on this perennially difficult content)
- Chapter Reviews (downloadable expanded key points for each chapter)
- Health Assessment Image Collection (supplemental images of common assessment findings)
- Audio Glossary
- Audio Clips, Animations, and Video Clips
- Content Updates

For more information on any of these innovative companion resources, contact your Elsevier Educational Solutions Consultant, visit <http://www.us.elsevierhealth.com/>, or contact Elsevier Faculty Support at 1-800-222-9570 or sales.inquiry@elsevier.com.

In summary, *Medical-Surgical Nursing: Patient-Centered Collaborative Care*, 7th edition, together with its fully integrated multimedia ancillary package, provides the tools you will need to meet the challenge of nursing in the second decade of the 21st century and beyond. The only elements that remain to be added to this package are those that you alone can provide—your diligence, your commitment, your innovation, *your nursing expertise*.

Donna D. Ignatavicius
M. Linda Workman

To Charles and Stephanie
Thank you for your unending support, love, and understanding
during every edition; I could not do this without you!
Stephanie, I especially appreciate your editorial help.

To students and faculty
Thank you for your feedback, support, and guidance
during my journey as an author over many years.

Donna

To students everywhere, who inspire us to make each edition better.

To GBW: Your courage and integrity are limitless.

Linda

ABOUT THE AUTHORS

Donna D. Ignatavicius received her diploma in nursing from the Peninsula General School of Nursing in Salisbury, Maryland. After working as a charge nurse in medical-surgical nursing, she became an instructor in staff development at the University of Maryland Medical Center. She then received her BSN from the University of Maryland School of Nursing. For 5 years she taught in several schools of nursing while working toward her MS in Nursing, which she received in 1981. Donna then taught in the BSN program at the University of Maryland, after which she continued to pursue her interest in gerontology and accepted the position of Director of Nursing of a major skilled-nursing facility in her home state of Maryland. Since that time, she has served as an instructor in several associate degree nursing programs. Through her consulting activities and faculty development workshops, Donna has gained national recognition in nursing education. She is currently the President of DI Associates, Inc. (<http://www.diassociates.com/>), a company dedicated to improving health care through education and consultation for faculty. In recognition of her contributions to the field, she was inducted as a charter Fellow of the prestigious Academy of Nursing Education in 2007.

M. Linda Workman, a native of Canada, received her BSN from the University of Cincinnati College of Nursing and Health. After serving in the U.S. Army Nurse Corps and working as an Assistant Head Nurse and Head Nurse in civilian hospitals, Linda earned her MSN from the University of Cincinnati College of Nursing and a PhD in Developmental Biology from the University of Cincinnati College of Arts and Sciences. Linda's 30-plus years of academic experience include teaching at the diploma, associate degree, baccalaureate, and master's levels. Her areas of teaching expertise include medical-surgical nursing, physiology, pathophysiology, genetics, oncology, and immunology. Linda has been recognized nationally for her teaching expertise and was inducted as a Fellow into the American Academy of Nursing in 1992. She received Excellence in Teaching awards at the University of Cincinnati and at Case Western Reserve University. She is a former American Cancer Society Professor of Oncology Nursing and held an endowed chair in oncology for 5 years. In addition to authoring several textbooks and serving as a consult for major universities, she is Senior Volunteer Faculty at the College of Nursing, University of Cincinnati.

ACKNOWLEDGMENTS

Publishing a textbook and ancillary package of this depth and breadth would not be possible without the combined efforts of many people. Stephanie M. Ignatavicius assisted with literature searches and the revision of [Chapter 4](#) (Cultural Aspects of Health and Illness). Paul W. Elliott, Jr. helped develop the Concept Overview feature for Mobility, Sensation, and Cognition.

Our contributing authors once again provided consistently excellent manuscripts in a timely fashion. Special thanks to Deanne Blach, who redesigned our Concept Maps. Our reviewers—expert clinicians and instructors from around the United States and Canada—provided invaluable suggestions and encouragement throughout the book's development.

The staff of Elsevier/Saunders once again provided us with crucial guidance and support throughout the planning, writing, revision, and production of the seventh edition. In particular, Executive Content Strategist Lee Henderson worked closely with us from the early stages of this edition to help us hone and focus our revision plan, and Lee coordinated the project from start to finish. Senior Content Development Specialist Rae Robertson then worked with us step-by-step to bring the seventh edition from vision to publication. Rae, Julia Curcio, and Kelly McGowan held the reins of our complex ancillary package and worked with a gifted group of writers and content experts to provide an outstanding library of resources to complement and enhance the text. Special thanks to Content Coordinator Kelly McGowan, who not only managed the *Clinical Companion* but also handled the countless administrative details associated with a project of this size.

Senior Project Manager Jodi Willard was once again a joy to work with. If, as is said, the mark of a good editor is that her work is invisible to the reader, then Jodi is the consummate editor. Her unwavering attention to detail, flexibility, and conscientiousness not only helped to make this edition the most consistently readable ever, but also made the entire production process incredibly smooth.

Special thanks also to Publishing Services Manager Debbie Vogel. For three editions now, Debbie has worked quietly behind the scenes to help bring the book to publication precisely on schedule and with a very high level of quality.

Designer Paula Catalano is responsible for the beautiful cover and the completely new interior design of the seventh edition. The praise of a book designer's work is often unsung, but Paula's work on this edition has cast important features in exactly the right light, with neither too much nor too little emphasis, making this edition not only practical and easy to read, but also beautiful.

Our acknowledgments would not be complete without recognizing our dedicated team of Educational Solutions Consultants and other key members of the Sales and Marketing staff who helped to put this book into your hands.

Finally, we wish to thank Sally Schreffer (Managing Director, Nursing and Health Professions), Loren Wilson (Vice President and Publisher, Nursing), Tom Wilhelm (Vice President, eSolutions, Nursing), and Robin Carter (Director, eContent Solutions, Nursing) for their ongoing vision, direction, and support for state-of-the-art educational resources for nurses.

GUIDE TO SPECIAL FEATURES

ASSESSMENT USING GORDON'S FUNCTIONAL HEALTH PATTERNS

Acid-Base Assessment, 204
Cardiovascular Assessment, 693
Ear and Hearing Assessment, 1080
Endocrine Assessment, 1366
Eye and Vision Assessment, 1045
Fluid and Electrolyte Assessment, 175
Gastrointestinal Assessment, 1182
Hematologic Assessment, 861
Musculoskeletal Assessment, 1110
Neurologic Assessment, 914
Renal/Urinary Assessment, 1474
Reproductive Assessment, 1580
Respiratory Assessment, 550

BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Acute Adrenal Insufficiency, 1382
AIDS, Infection Control for Home Care, 379
Altitude-Related Illnesses, Preventing, Recognizing, and Treating, 152
Alzheimer's Disease, Promoting Communication, 952
Anaphylaxis, 390
Anterior Nosebleed, 582
Anticoagulant Therapy, 801
Anticoagulant, Fibrinolytic, or Antiplatelet Therapy, Prevention of Injury, 668
Arteriovenous Fistula or Arteriovenous Graft, 1562
Artificial Airway, Suctioning, 574
Aspiration Prevention During Swallowing, 577, 595
Autologous Blood Salvage and Transfusion, 278
Autonomic Dysreflexia, 974
Benzodiazepine Overdose, 293
Breast Mass Assessment, 1598
Breast Reconstruction, Postoperative Care, 1605
Burns, 520
Cancer, Colorectal, Screening Recommendations, 1246
Cancer, Gynecologic, Brachytherapy, 1623
Caregiver Stress Reduction, 954
Carpal Tunnel Syndrome Prevention, 1171
Catheter-Related Infection Prevention, 1492
Cervical Discectomy and Fusion, 966
Chest Discomfort, 836
Chest Tube Drainage Systems, 637
Colonoscopy, 1190
Communicating with Non-English-Speaking Patients, 33
Communicating with Patients Unable to Speak, 587
Continuous Passive Motion Machine, 330
Contracture Prevention, 537
Contrast Agent Precautions for Diagnostic Testing, 921
Contrast Media, Assessing the Patient, 1484
Dark Skin, Assessing Changes, 467
Dehydration, 177

Diarrhea, Skin Care, 1263
Driver Safety Improvement, Older Adults, 20
Dying Patient and the Family, Psychosocial Interventions, 116
Dysrhythmias, 731
Ear Irrigation, 1091
Eardrops Instillation, 1089
Electroencephalogram, 922
Emergency Department, Maintaining Patient and Staff Safety, 124
Endocrine Testing, 1369
Endotracheal Tube, Oral and Nasal, 676
Energy Conservation, 890
Extravasation Documentation, 417
Extremity Fracture, 1150
Eye Patch Application, 1055
Eyedrops Instillation, 1050
Fall Prevention in Older Adults, 27
Falls Precautions, 176
Feeding Tube Maintenance, 1346
Fires in Health Care Facility, Response, 156
Fluid Resuscitation for Burns, 526
Fluid Volume Management, 1553
Fundoplication, Assessment of Complications, 1211
Gait Training, 98
Genetic Testing and Counseling, 76
Genital Herpes, 1657
Hand Hygiene, 438
Hearing Impairment and Communication, 1103
Heart Transplant Rejection, 770
Heat Stroke, 139
Hemodialysis, 1563
HIV, Occupational Postexposure Prophylaxis, 364
HIV, Recommendations for Preventing Transmission by Health Care Workers, 364
Home Hospice, Symptom Relief, 118
Hypertensive Crisis, 784
Hypokalemia, 185
Hypophysectomy, 1377
Hypovolemic Shock, 818
Immunosuppressed Patient, 371
Infection Risks, 437
Inflammatory Bowel Disease, Pain Control and Skin Care, 1278
Intraoperative Positioning, Prevention of Complications, 281
Lumbar Spinal Surgery, Assessment and Management of Complications, 964
Magnetic Resonance Imaging, 1116
Malignant Hyperthermia, 273
Mechanical Ventilation, 677
Meningitis, 939
Mental Status Assessment, 914
Musculoskeletal Injury, Assessment of Neurovascular Status, 1149
Myasthenia Gravis, Improving Nutrition, 995
Myelosuppression, 420
Myxedema Coma, 1403

Nasogastric Tube After Esophageal Surgery, 1216
 Nasogastric Tubes, 1232
 Neutropenia, 420
 Nursing Database, 913
 Nutritional Screening Assessment, 1337
 Ocular Irrigation, 1072
 Ocular Prosthesis, Insertion and Removal, 1073
 Ophthalmic Ointment Instillation, 1053
 Opioid Overdose, 299
 Oral Cavity Problems, 1194
 Osteoporosis and Assessment of Risk Factors, 1120
 Oxygen Therapy, 563
 Pain, Reducing Postoperatively with Nonpharmacologic Interventions, 299
 Paracentesis, 1300
 Parkinson Disease, 943
 Pericarditis, 766
 Perineal Comfort Promotion, 1287
 Perineal Wound Care, 1251
 Peripheral Venous Catheters, Placement, 214
 Peritoneal Dialysis Catheter, 1567
 Phlebostatic Axis Identification, 708
 Plasmapheresis Complications, 989
 Postmortem Care, 119
 Postoperative Hand-off Report, 285
 Post-Traumatic Stress Disorder Prevention in Staff During a Mass Casualty Event, 162
 Pressure Ulcer Prevention, 476
 Pressure Ulcers and Wound Management, 483
 Prostatectomy, 1639
 Pulmonary Embolism Care, 665
 Pulmonary Embolism Prevention, 663
 Radioactive Sealed Implants, 413
 Recombinant Tissue Plasminogen Activator Administration, Nursing Interventions, 1014
 Relocation Stress in Older Adults, Minimizing Effects, 19
 Reproductive Health Problems, 1580
 Restraint Alternatives, 28
 Sick Cell Crisis, 874
 Sinus Surgery, 642
 Skin Problems, Nursing History, 458
 Spinal Cord Injury and Motor Function Assessment, 969
 Sports-Related Injuries, 1169
 Surgical Wound Evisceration, 296
 Systemic Sclerosis and Esophagitis, 348
 Thrombocytopenia, 889
 Thrombocytopenia, Prevention of Injury, 421
 Thyroid Storm, 1400
 Tonic-Clonic or Complete Partial Seizure, 935
 Total Parenteral Nutrition, 1348
 Tracheostomy Care, 576
 Transfer Techniques, 97
 Transfusion Therapy, 898
 Transfusion, Older Adult, 899
 Transurethral Resection of the Prostate, 1636
 Tube Feeding Care and Maintenance, 1345
 Urinary Incontinence Reduction with Bladder Training and Habit Training, 1504
 Ventilator-Associated Pneumonia Prevention, 648
 Vertebroplasty or Kyphoplasty, Nursing Care, 1163
 Viral Hepatitis Prevention in Health Care Workers, 1307
 Vision Reduction, Care, 1074

Wandering, Prevention in Hospitalized Patients, 953
 Wound Monitoring, 489
 Z-Track Injection Method, 877

COMMON EXAMPLES OF DRUG THERAPY

Adrenal Gland Hypofunction, 1384
 Anaphylaxis, 390
 Anthrax, Prophylaxis and Treatment, 659
 Antiepileptic Drugs, 934
 Arthritis and Connective Tissue Disease, 338
 Asthma, 607
 Burns, 534
 Cardiac Arrest, 734
 Coronary Artery Disease, 838
 Diabetes Insipidus, 1379
 Diabetes Mellitus, 1423
 Dysrhythmias, 723
 Eye Inflammation and Infection, 1054
 Gastroesophageal Reflux Disease, 1207
 Glaucoma, 1066
 HIV Infection, 372
 Hypertension, 781
 Hyperthyroidism, 1398
 Hypovolemic Shock, 819
 Kidney Disease, 1544
 Methicillin-Resistant *Staphylococcus aureus*, 495
 Nausea and Vomiting, Chemotherapy-Induced, 423
 Osteoporosis, 1126
 Pain, Postoperative, 298
 Peptic Ulcer Disease, 1223
 Plaque Psoriasis, 501
 Pulmonary Embolism, 666
 Tuberculosis, 656
 Urinary Incontinence, 1502
 Urinary Tract Infections, 1495
 Vasodilators and Inotropes, Intravenous, 843

CONCEPT MAP

Bacterial Pneumonia, 649
 Benign Prostatic Hyperplasia, 1634
 Cancer Pain, Chronic, 42
 Cirrhosis, 1301
 Diabetes Mellitus—Type 2, 1422
 End-Stage Kidney Disease, 1554
 Glaucoma, 1064
 Hypertension, 779
 Hypovolemic Shock, 815
 Multiple Sclerosis, 981
 Pressure Ulcer, 484
 Respiratory Acidosis (COPD Related), 615

EVIDENCE-BASED PRACTICE

Analgesic Use in Older Adults with Pain and Dementia, 50
 Atrial Fibrillation and Obesity, 727
 Blood Pressure Self-Management, 785
 Bowel Control and Manual Disimpaction in Patients with Spinal Cord Injury, 103
 Breast Cancer and Dietary Soy Intake, 1600
 Burns and Music Therapy, 529

Cardiac Events and Post-Acute Care Programs, 851
 Colonoscopy, Pain and Anxiety Reduction, 1189
 Depression and Despair in Older Adults, Improvement Through Reflective Activities, 24
 Diabetes and Missed Prescribed Insulin Doses, 1432
 Emergency Department Visits and Homeless Adults, 130
 End-of-Life Care, Cultural Preferences in Developed Countries, 110
 Fractured Hip and Best Practices for Acute Pain Management, 1161
 Guideline Implementation, 253
 Hearing Loss in Older Adults, 1099
 Heart Failure Patients, Telephone Visits and Quality of Life, 758
 Heat Stroke, Predicting Factors, 138
 Hematopoietic Stem Cell Transplantation and Infection Prevention, 888
 Intestinal Ostomies and Sexuality Challenges in Men, 1253
 Mechanical Ventilation and Turning, 673
 Medication Error Prevention Recommendations, 732
 Multiple Sclerosis and Sexual Function, 980
 Oral Hygiene in Older Adults, 1193
 Osteoporosis Diagnosis in Skilled Nursing Facilities, 1122
 Pain, Effect of Music Therapy and Relaxation Compared with Pain Management Teaching, 12
 Parkinson's Disease, Telehealth Technology, and Learning, 945
 Radiation Skin Effects and Skin Care Products, 414
 Septic Shock and Procalcitonin Levels, 824
 Smoking Cessation and Confidence, 598
 Strokes, Rates of Recurrence in Various Ethnic Groups, 1008
 Urinary Diversion for Bladder Cancer and Sexual Expression, 1515

FOCUSED ASSESSMENT

AIDS, 379
 Cancer, Oral, Older Adults, 1199
 Diabetic Foot, 1447
 Diabetic Patient, Home or Clinic Visit, 1461
 Hearing Loss, 1099
 Hysterectomy, Total Abdominal, 1620
 Infection Risk, 883
 Kidney Disease, Chronic, 1571
 Pneumonia, 652
 Postanesthesia Care Unit Discharge to Medical-Surgical Unit, 288
 Preoperative Patient, 250
 Seizures, Nursing Observations and Documentation, 936
 Sexually Transmitted Disease, 1655
 Testicular Lump, 1644
 Tracheostomy, 576
 Urinary Incontinence, 1500

HOME CARE ASSESSMENT

Amputation, Lower Extremity, 1168
 Breast Cancer Surgery, 1608
 Cataract Surgery, 1062
 Chronic Obstructive Pulmonary Disease, 623
 Colostomy, 1253

Heart Failure, 756
 Hyperpituitarism, Transsphenoidal or Endoscopic Nasal Hypophysectomy, 1377
 Inflammatory Bowel Disease, 1280
 Laryngectomy, 596
 Myocardial Infarction, 850
 Peripheral Vascular Disease, 791
 Pressure Ulcers, 490
 Pulmonary Embolism, 669
 Sepsis, 826
 Thyroid Dysfunction, 1405
 Ulcer Disease, 1233

KEY FEATURES

Acidosis, 204
 Adrenal Insufficiency, 1382
 AIDS, 365
 Alkalosis, 208
 Alzheimer's Disease, 948
 Amyotrophic Lateral Sclerosis, 983
 Anaphylaxis, 389
 Anemia, 871
 Angina and Myocardial Infarction, 835
 Anthrax, 659
 Asthma Control and Step System for Medication, 604
 Asthma, 603
 Autonomic Dysreflexia, 973
 Bowel Obstructions, Small and Large, 1255
 Brain Tumors, 1032
 Cancer, Gastric, Early Versus Advanced, 1235
 Cancer, Oral, 1196
 Cancer, Pancreatic, 1330
 Cervical Discectomy and Fusion, 967
 Cholecystitis, 1317
 Compartment Syndrome, 1146
 Cor Pulmonale, 614
 Diabetes Insipidus, 1378
 Endocarditis, Infective, 764
 Fluid Overload, 179
 Gastritis, 1222
 Gastroesophageal Reflux Disease, 1204
 GI Bleeding, 1227
 Giant Cell (Temporal) Arteritis, 351
 Guillain-Barré Syndrome, 987
 Heart Failure, Left-Sided, 749
 Heart Failure, Right-Sided, 749
 Heat Stroke, 138
 Hernias, 1209

CHAPTER

1

Introduction to Medical-Surgical Nursing

Donna D. Ignatavicius

<http://evolve.elsevier.com/Iggy/>Audio Glossary
Key Points

Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

1. Describe the scope of medical-surgical nursing.
2. Explain the recent increased focus on patient safety and quality of care.
3. Identify the purpose of the Rapid Response Team (RRT).
4. Explain when to call the RRT.
5. Differentiate the six core competencies that health care professionals need to provide safe, quality health care.
6. Identify three ethical principles that help guide clinical decision making.
7. Explain the importance of communication when collaborating with the interdisciplinary team.
8. Outline the five rights of the delegation and supervision process.
9. Describe the SBAR procedure for successful communication in health care agencies.
10. Describe the nurse's role in the systematic quality improvement process.
11. Identify three ways that informatics and technology are used in health care.

The scope of medical-surgical nursing, sometimes called *adult health nursing*, is to promote health and prevent illness or injury in patients from 18 to older than 100 years of age. A separate chapter on care of older adults is part of this textbook because the majority of medical-surgical patients are older than 65 years (see [Chapter 3](#)). To be consistent with the most recent health care literature, the authors use the term *patient* rather than *client* (except in *NCLEX Examination*

Challenge questions). The *family* refers to the patient's relatives or significant others in the patient's life.

The primary focus of medical-surgical nursing care is to meet the biologic, psychosocial, cultural, and spiritual needs of the adult patient in a mutually trusting, respectful, and caring relationship. These basic needs, also referred to as *concepts*, were introduced in your Fundamentals of Nursing course. This textbook builds on those concepts but focuses

most on the role of nurses in meeting biologic (physiologic) needs for patients with selected medical-surgical health problems. Discussions of psychosocial (emotional), cultural, and spiritual needs are presented when appropriate to describe a holistic approach to patient care.

To further build a bridge between your basic fundamentals course and medical-surgical nursing care, several special features at the beginning of each textbook section review these selected concepts:

- Protection
- Oxygenation and Tissue Perfusion
- Mobility, Sensation, and Cognition
- Nutrition, Metabolism, and Bowel Elimination
- Urinary Elimination
- Sexuality

Nurses who practice medical-surgical nursing must have a broad knowledge base to meet the needs of patients in a variety of health care settings across the continuum (Academy of Medical-Surgical Nursing [AMSN], 2007). Rapid advances in technology, massive increases in knowledge, and dramatic changes in the health care delivery system require that medical-surgical nurses use expert clinical judgment to ensure patient safety as the priority in practice.

Health care errors by physicians, nurses, and other health care professionals have been widely publicized for the past 15 years. Many of these errors have resulted in patient deaths and injuries and increased health care costs. As a result of these findings, a number of national and international organizations have implemented new programs and standards to combat this growing problem.

NATIONAL PATIENT SAFETY GOALS

In 2000, the Institute of Medicine (IOM) stated in its *To Err is Human: Building a Safer Health Care System* publication that between 44,000 and 98,000 patient deaths result each year from preventable errors in acute care hospitals. The report identified several factors that contribute to these findings and motivated other national bodies to examine ways they could improve patient safety and quality care. One of these groups, The Joint Commission (TJC), requires that health care organizations create a *culture of safety and encourage patients and families to become safety partners in protecting patients from harm*.

The **Joint Commission** is a national organization that offers peer evaluation for accreditation every 3 years for all types of U.S. health care agencies that meet their standards. Although acute care hospitals are accredited more often than other types of settings, many home care agencies, nursing homes, and ambulatory care centers are also TJC-accredited. Some agencies chose accreditation by other organizations other than TJC, but safety is a major focus for all of them.

In 2002, TJC published its first annual **National Patient Safety Goals (NPSGs)**. These Goals require health care organizations to focus on specific priority safety practices, many of which involve nursing care. Since that time, TJC continues to add new Goals each year. NPSGs address high-risk issues such as drug administration, fall reduction, pressure ulcer prevention, and communication among health care team members. When appropriate, this textbook discusses related NPSGs. A complete list of these goals can be found on TJC website at www.jointcommission.org.

TABLE 1-1 IHI INTERVENTIONS TO SAVE PATIENT LIVES AND PREVENT PATIENT HARM

INTERVENTIONS TO SAVE PATIENT LIVES	INTERVENTIONS TO PREVENT PATIENT HARM
Deploy Rapid Response Teams.	Prevent harm from High-Alert Drugs (e.g., anticoagulants, insulin, opioids).
Provide reliable, evidence-based care for acute myocardial infarction.	Reduce surgical complications.
Prevent central line infections.	Prevent pressure ulcers.
Prevent adverse drug events (ADEs).	Reduce methicillin-resistant <i>Staphylococcus aureus</i> (MRSA) infections.
Prevent surgical site infections (SSIs).	Provide reliable, evidence-based care for congestive heart failure.
Prevent ventilator-associated pneumonia (VAP).	Get boards of health care organizations to support measures to promote safe patient care.

IHI, Institute for Healthcare Improvement.

PROTECTING FIVE MILLION LIVES FROM HARM

As a result of the IOM report and other data from national studies, the Institute for Healthcare Improvement (IHI) estimates that there are nearly 15 million health care errors in U.S. hospitals each year, or 40,000 per day (IHI, 2005). In 2004, the IHI and its partner health care organizations launched the *100,000 Lives Campaign*—an effort to save patient lives over an 18-month targeted time frame. Six interventions for quality improvement changes in care were implemented by partnering health care agencies (Table 1-1). As a result of this project, an estimated 122,000 patient lives were saved!

The next IHI objective was to *protect patients from five million incidents of medical harm* over a 2-year period (December 2006–December 2008) (IHI, 2005). **Medical harm** refers not just to physician incidents but to errors caused by all members of the health care team or system that lead to patient injury or death. To meet this IHI objective, six interventions for changes in care were added to the original list. As seen in Table 1-1, many of these interventions are within the scope of nursing practice and are therefore emphasized throughout this textbook. Some interventions, such as pressure ulcer prevention and adverse drug event reduction, are also part of TJC's National Patient Safety Goals.

One of the most successful IHI initiatives was the creation of the Rapid Response Team (RRT), also called the *Medical Emergency Team (MET)*. **Rapid Response Teams** save lives

! NURSING SAFETY PRIORITY

Critical Rescue

Early clinical changes in condition occur in most patients for up to 48 hours before a "Code Blue." Therefore observe for, document, and communicate early indicators of patient decline, including decreasing blood pressure, increasing heart rate, and changes in mental status.

and decrease the risk for harm by providing care to patients *before* a respiratory or cardiac arrest occurs. Although the RRT does not replace the Code Team who responds to patient arrests, it intervenes rapidly when needed for those who are *beginning* to clinically decline.

Members of an RRT are critical care experts who are on-site and available at any time. Although membership varies among facilities, the team may consist of an ICU nurse, respiratory therapist, **intensivist** (physician who specializes in critical care), and/or **hospitalist** (family practitioner or internist employed by the hospital). In other hospitals, acute care nurse practitioners or medical residents may be part of the team. The team responds to emergency calls, usually from nurses, according to established agency protocols and policies. Patient families may also activate the RRT (Bogert et al., 2010). Outcome data demonstrate that the RRT approach to emergency care reduces medical complications and decreases the number of cardiac and respiratory arrests.

TJC's National Patient Safety Goals also include the need for early intervention for patients who are clinically changing. They require each health care organization to establish criteria for patients, families, or staff to call for additional assistance in response to an actual or perceived change in the patient's condition.

INSTITUTE OF MEDICINE/QUALITY AND SAFETY EDUCATION FOR NURSES CORE COMPETENCIES

The Institute of Medicine (IOM) published many reports during the past 15 years suggesting ways to improve patient safety and quality care. One of its reports, *Health Professions Education: A Bridge to Quality*, identified five broad core competencies for health care professionals to ensure patient safety and quality care (IOM, 2003). All of these competencies are interrelated and include:

- Provide patient-centered care.
- Collaborate with the interdisciplinary health care team.
- Implement evidence-based practice.

- Use quality improvement in patient care.
- Use informatics in patient care.

Several years later, the Quality and Safety Education for Nurses (QSEN) initiative validated the IOM competencies for nursing practice and added *safety* as a separate competency to emphasize its importance. In addition, the QSEN project team created specific knowledge, skills, and attitudes (KSAs) needed to develop each core competency, using a Delphi research approach.

This text highlights the QSEN competencies in its *Decision-Making Challenges*. Teaching/learning activities to help students develop specific KSAs can be found in the *Instructor Resources (IR)* on the *Evolve* website and accompanying *Student Study Guide*. Each QSEN competency is briefly described in the following six sections.

Patient-Centered Care

To be competent in **patient-centered care**, the medical-surgical nurse recognizes “the patient or designee as the source of control and full partner in providing compassionate and coordinated care based on respect for [the] patient’s preferences, values, and needs” (*Quality and Safety Education for Nurses [QSEN]*, 2011). The KSAs for competence in patient-centered care focus on communication, compassion, culture, patient education and empowerment, and respect for patients and their families (Table 1-2).

Nurses also provide family-centered care. As an advocate for the patient and family, teach them how to be empowered and have more control over their care. To assist in this process, The Joint Commission recently started a Speak Up™ campaign to provide information to patients and families to increase their empowerment (The Joint Commission, 2011). The basic framework of the campaign urges patients and their families to:

- **Speak up** if you have questions or concerns, and if you don’t understand, ask again. It’s your body and you have a right to know.
- **Pay attention** to the care you are receiving. Make sure you’re getting the right treatments and medications by the right health care professionals. Don’t assume anything.

TABLE 1-2 EXAMPLES OF KNOWLEDGE, SKILLS, AND ATTITUDES NEEDED TO DEVELOP THE IOM/QSEN PATIENT-CENTERED CARE COMPETENCY

KNOWLEDGE	SKILLS	ATTITUDES
Describe how diverse cultural, ethnic, and social backgrounds function as sources of patient, family, and community values.	Provide patient-centered care with sensitivity and respect for the diversity of human experience.	Recognize personally held attitudes about working with different ethnic, cultural, and social backgrounds.
Demonstrate comprehensive understanding of the concepts of pain and suffering, including physiologic models of pain and comfort.	Assess presence and extent of pain and suffering.	Recognize personally held values and beliefs about the management of pain and suffering.
Examine how the safety, quality, and cost-effectiveness of health care can be improved through the active involvement of patients and families.	Engage patients or designated surrogates in active partnerships that promote health, safety and well-being, and self-care management.	Respect patient preferences for degree of active engagement in care processes.
Explore ethical and legal implications of patient-centered care.	Facilitate informed patient consent for care.	Respect and encourage individual expression of patient values, preferences, and expressed needs.

Data from Quality and Safety Education for Nurses, 2011 (www.qsen.org).
IOM, Institute of Medicine; QSEN, Quality and Safety Education for Nurses.

- **E**ducate yourself about your diagnosis, the medical tests you are undergoing, and your treatment plan.
- **A**sk a trusted family member or friend to be your advocate.
- **K**now what medications you take and why you take them. Medication errors are the most common health care errors.
- **U**se a hospital, clinic, surgery center, or other type of health care organization that has undergone a rigorous on-site evaluation against established state-of-the-art quality and safety standards, such as that provided by The Joint Commission.
- **P**articipate in all decisions about your treatment. You are the center of the health care team.

Patient empowerment is one way to demonstrate respect for patients in their ability to be care partners. Respect for people is the basis for three essential *ethical principles* that nurses and other health care professionals should use as a guide for clinical decision making. Respect implies that patients are treated as autonomous individuals capable of making informed decisions about their care. This patient autonomy is referred to as **self-determination** or **self-management**. When the patient is not capable of self-determination, you are ethically obligated to protect him or her as an advocate within the professional scope of practice, according to the American Nurses Association (ANA) Code of Ethics for Nurses (Fowler, 2008).

The second ethical principle is **beneficence**, which emphasizes the importance of preventing harm and ensuring the patient's well-being. Harm can be avoided only if its causes or possible causes are identified. As described earlier in this chapter, patient safety is currently a major national focus to prevent deaths and injuries.

Social justice, the third principle, refers to equality; that is, all patients should be treated equally and fairly. For example, a patient who cannot afford health care should receive the same quality and level of care as one who has extensive insurance coverage. An older patient with dementia should be shown the same respect as a younger patient who can communicate.

Teamwork and Collaboration

To provide patient- and family-centered care, the nurse “functions effectively within nursing and inter-professional teams, fostering open communication, mutual respect, and shared decision-making to achieve quality patient care” (QSEN, 2011). Therefore the KSAs for this competency emphasize the importance of communication and team functioning. Communication is an essential process for successful collaboration. **Collaboration** entails planning, implementing, and evaluating patient care together using an interdisciplinary (ID) plan of care. To help meet this purpose, health care agencies have frequent and regular ID meetings and conduct ID patient care rounds.

Electronic mail (e-mail) allows for quick communication among health care professionals to enhance collaboration and coordination of care. *However, it should not replace face-to-face and phone communication.*

While there are many health care team members, some caregivers work more closely with nurses than others. For example, the physician or other health care provider and medical-surgical nurse collaborate frequently in a given day

regarding patient care. The occupational therapist may not work as closely with the nurse unless the patient is receiving rehabilitation services. Collaboration with the rehabilitation team is discussed in **Chapter 8**.

One of the most important members of the ID team is the case manager (CM), who is typically a nurse or social worker in acute care hospitals. The purpose of the **case management** process is to provide quality and cost-effective services and resources to achieve positive patient outcomes. In collaboration with the nurse, the CM coordinates inpatient and community-based care before discharge from a hospital or other facility. Part of that process may involve communicating with other CMs who are employed by third-party health care payers (e.g., Medicare).

Communication

Poor communication between professional caregivers and health care agencies causes many medical errors and patient safety risks. In 2006, The Joint Commission began to require systematic strategies for improving communication. Two years later, another National Patient Safety Goal mandated that nurses communicate continuing patient care needs, such as pain management or respiratory support, to post-discharge caregivers.

To improve communication between staff members and health care agencies, procedures for hand-off communication were established. A popular procedure used in many agencies today is called SBAR (pronounced S-Bar). **SBAR** is a formal method of communication between two or more members of the health care team. The SBAR process includes these four steps:

- **Situation:** Describe what is happening at the time to require this communication.
- **Background:** Explain any relevant background information that relates to the situation.
- **Assessment:** Provide an analysis of the problem or patient need based on assessment data.
- **Recommendation:** State what is needed or what the desired outcome is.

Several modifications of SBAR include I-SBAR and I-SBAR-R. In these procedures, the “I” reminds the individual to identify himself or herself. The last “R” stands for the response that the receiver provides based on the information given.

Other agency-specific hand-off communication methods may be used. For example, Schroeder (2006) described a method for patient reporting called *PACE*. PACE stands for Patient Problem, Assessment/Actions, Continuing/Changes, and Evaluation. This type of focused information helps the receiving nurse maintain continuity of care and address any new patient problems that may have occurred. Be sure to follow the established documentation and reporting protocols in your agency.

One of the most recent projects to improve communication was provided in 2010 by the Center for Transforming Health Care (www.centerfortransforminghealthcare.org). Every transition of care is potentially risky for patients because vital information needs to be communicated among caregivers and from one health care agency to another to keep patients safe. This quality improvement (QI) project recommends these targeted solutions to ensure successful communication using the acronym **SHARE** as outlined in **Table 1-3**.

TABLE 1-3 CENTER FOR TRANSFORMING HEALTH CARE TARGETED SOLUTIONS TO ENHANCE SUCCESSFUL HAND-OFF COMMUNICATION: SHARE

TARGETED SOLUTION	DESCRIPTION OF SOLUTION
S tandardize critical content.	Providing details of the patient's history to the receiver, emphasizing key information about the patient, and synthesizing information from various sources before passing it on.
H ardwire within your system.	Developing standardized forms, tools, and methods, such as checklists; identifying new and existing technologies to assist in successful hand-off; and stating expectations about how to conduct a successful hand-off.
A llow opportunity to ask questions.	Using critical-thinking skills when discussing a patient's case as well as sharing and receiving information as an interdisciplinary team ("pit crew"). Receivers should expect to receive all key information about the patient, scrutinize and question the data, and exchange contact information with the sender for additional questions.
R einforce quality and measurement.	Demonstrating leadership commitment to successful hand-offs, such as holding staff accountable, monitoring compliance with use of standardized forms, and using data to determine a systematic approach for improvement.
E ducate and coach.	Teaching staff throughout the organization about what constitutes a successful hand-off, standardizing training on how to conduct a hand-off, providing performance feedback at the time of the hand-off, and making successful hand-offs an organizational priority.

Data from The Joint Commission Center for Transforming Healthcare. (2010). Joint Commission Center for Transforming Healthcare tackles miscommunication among caregivers. Retrieved July 2, 2011, from www.centerfortransforminghealthcare.com.

Delegation and Supervision

As a nursing leader, you will delegate certain nursing tasks and activities to unlicensed assistive personnel (UAP), such as patient care technicians (PCTs) or patient care assistants (PCAs). **Delegation** is the process of transferring to a competent person the authority to perform a selected nursing task or activity in a selected patient care situation. This process requires precise and accurate communication. *The nurse is always accountable for the task or activity that is delegated!*

An important process that is sometimes not consistently performed by busy medical-surgical nurses is supervision of the UAP to whom the task or activity has been delegated. **Supervision** is guidance or direction, evaluation, and follow-up by the nurse to ensure that the task or activity is performed appropriately (National Council of State Boards of Nursing, 1995). Examples of delegated tasks are turning and positioning, vital signs, and intake and output measurements.

Be sure to follow these five rights when you delegate and supervise a nursing task or activity to a UAP:

- **Right task:** The task is within the UAP's scope of practice and competence.
- **Right circumstances:** The patient care setting and resources are appropriate for the delegation.
- **Right person:** The UAP is competent to perform the delegated task or activity.
- **Right communication:** The nurse provides a clear and concise explanation of the task or activity, including limits and expectations.
- **Right supervision:** The nurse appropriately monitors, evaluates, intervenes, and provides feedback on the delegation process as needed.

Other activities or patient care responsibilities may be assigned by an RN to another RN or to a licensed practical or vocational nurse (LPN/LVN). Each state designates which tasks may be safely delegated and assigned to nursing team members. Interventions that you can typically delegate or assign in any state are indicated throughout this text. Some of the *NCLEX Examination Challenges* throughout this book

will test your understanding of the delegation and supervision process.

Evidence-Based Practice

Evidence-based practice (EBP) is the integration of the best current evidence to make decisions about patient care. It considers the patient's preferences and values, as well as one's own clinical expertise for the delivery of optimal health care (Melnik & Fineout-Overholt, 2011; QSEN, 2011).

The best source of evidence is research. However, available nursing research is limited and, in some areas, may not reflect the highest or best level of evidence. Some nursing research is designed as small, descriptive studies to explore new concepts. The findings of these studies cannot be generalized, but they provide a basis for future larger and better-controlled research.

This edition of our text devotes a new chapter devoted to EBP (Chapter 7). In addition, *Evidence-Based Practice* boxes are found throughout the text to provide the most current research that serves as a basis for nursing practice. Each of these features presents a brief summary of the research, identifies the level (strength) of evidence using the scales in Chapter 7, and concludes with a "Commentary: Implications for Practice and Research" discussion to help you apply the findings of the study to your daily practice.

Quality Improvement

Ensuring patient and staff safety requires individual and systematic evaluation and change. To meet the **quality improvement** competency, nurses are expected to "use data to monitor the outcomes of care processes and use improvement methods to design and test changes to continuously improve the quality and safety of health care systems" (QSEN, 2011). The KSAs stress the importance of learning how to use specific QI tools, participating in root cause analyses, and impacting changes in care processes.

As a medical-surgical nurse, you will be expected to:

- Identify indicators to monitor quality and effectiveness of health care.

FIG. 1-1 An electronic documentation system that is used at the bedside.

- Access and evaluate data to monitor the quality and effectiveness of health care.
- Recommend ways to improve care processes.
- Implement activities to improve care processes.

Additional information about the QI process can be found in nursing leadership and management resources.

Informatics

Informatics involves using information and technology to communicate, manage knowledge, mitigate error, and support decision-making (Yoder-Wise, 2011; QSEN, 2011). The emphasis of the KSAs for informatics is documentation, electronic data access, and data utilization.

Although most health care settings have information technology (IT) departments, nurses retrieve and use valuable information for patient care. The largest application of health care informatics is use of the electronic health record (EHR) (also called *electronic patient record [EPR]* or *electronic medical record [EMR]*) for documenting nursing and interdisciplinary care. Computers may be centrally located or at the patient's bedside or treatment room. Handheld mobile devices are becoming more popular because of their ease of use and portability (Fig. 1-1).

Another major purpose of informatics is for retrieval of data for the evidence-based practice process described in Chapter 7. The Internet provides ways to search for multiple sources of information very efficiently. However, all data sources must be evaluated for their credibility and reliability. Some health care agencies provide handheld mobile devices, such as the iPod Touch™, to health care professionals for data access and team communication via text or e-mail.

New technologies for patient, staff, and resource (inventory) management are emerging in health care agencies to promote patient safety and improve efficiency. An example

of these technologies is radio frequency identification (RFID). RFID allows any person or object to be tracked electronically. For example, patients wear electronic identification wristbands.

As a result of their large qualitative study, Fisher and Monahan (2008) found that staff, especially nurses, expressed concerns about the surveillance potential of these tracking systems, particularly related to privacy rights of both patients and staff. Nurses were also concerned about the additional work that would be added to their busy day. The authors concluded that RFID systems, like any technology, need to be designed and implemented to prevent increased workloads and preserve privacy.

Nurses need to be involved in decisions about introducing new or advanced health care technologies into the health care agency. They should also be included in designing technology that improves the effectiveness and efficiency of health care while providing for patient and staff privacy.

Safety

As discussed earlier in this chapter, nurses play a key role in promoting safety and preventing errors, including “missed nursing care.” The nurse “minimizes risk of harm to patients and providers through both system effectiveness and individual performance” (QSEN, 2011). The KSAs for safety stress the importance of examining care processes (QI), integrating national patient resources, and using appropriate tools to reduce reliance on memory, such as checklists.

The National Council of State Boards of Nursing (NCSBN) recently published findings of an extensive study of nursing practice breakdowns (Benner et al., 2010). These results identified nine key areas where nursing practice should be improved, including:

- Medication administration
- Clearly communicating patient data and clinical assessments
- Attentiveness/surveillance of patients
- Clinical reasoning or judgment
- Prevention of errors or complications
- Intervention (carrying out nursing actions in an appropriate and timely manner)
- Interpretation of authorized provider orders
- Professional responsibility and patient advocacy
- Mandatory reporting

The research report also provided case examples and analyses to assist in the development of quality improvement processes.

Three types of “Nursing Safety Priority” boxes are found throughout this text to emphasize the importance of safety when in daily practice. These features delineate safety based on patient need. For example, “Nursing Safety Priority: Critical Rescue” emphasizes the need for action for potential or actual life-threatening problems. “Nursing Safety Priority: Action Alert” boxes focus on the need for action but not necessarily for life-threatening situations. These safety alerts are essential, though, to ensure optimal patient outcomes. As the name implies, “Nursing Safety Priority: Drug Alert” boxes specify actions needed to ensure safety related to drug administration, monitoring, or related patient and family education.

GET READY FOR THE NCLEX® EXAMINATION!**KEY POINTS**

Review these Key Points.

- Medical-surgical nursing requires a broad knowledge base to meet the needs of adult patients in a variety of settings across the continuum.
- The Joint Commission requires that health care organizations create a *culture of safety* by following the National Patient Safety Goals (NPSGs).
- The Institute of Healthcare Improvement (IHI) interventions to save lives and prevent patient harm are listed in [Table 1-1](#).
- Rapid Response Teams (RRTs) save lives and decrease the risk for patient harm before a respiratory or cardiac arrest occurs.
- Remember to always observe for slow and sudden changes in patient condition, especially changes in vital signs and mental status.
- Medical-surgical nurses help meet human needs of adult patients, such as mobility and oxygenation, in a caring, mutually respectful relationship.
- A vital role of the nurse is as an advocate to empower patients and their families to have control over their health care.
- The six core competencies for health care professionals based on research by the Institute of Medicine (IOM) and Quality and Safety Education for Nurses (QSEN) are patient-centered care, teamwork and collaboration, evidence-based practice, quality improvement, informatics, and safety.
- Examples of the knowledge, skills, and attitudes needed for patient-centered care are found in [Table 1-2](#).
- Three essential ethical principles to consider when making clinical decisions are self-determination, beneficence, and justice.
- Nurses function as coordinators of care by communicating and collaborating with members of the health care team.
- The SBAR procedure or similar established protocol is used for successful communication between caregivers and between health care agencies.
- Evidence-based practice (EBP) is the integration of best current evidence to make decisions about patient care. It considers the patient's preferences and values, as well as one's own clinical expertise.
- Nurses are active participants in the systematic quality improvement process in their health care agency.
- Informatics and technology are used for patient documentation, electronic data access, and health care resource tracking.

Introduction to Complementary and Alternative Therapies

Donna D. Ignatavicius

Answer Key for NCLEX Examination Challenges and
Decision-Making Challenges
Audio Glossary

Key Points
Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

Health Promotion and Maintenance

1. Teach patients about uses, precautions, and adverse effects associated with using natural products.
2. Describe special considerations related to complementary and alternative medicine (CAM) usage among older adults.

Physiological Integrity

3. Identify the role of the nurse in using mind-body therapies.

4. Explain the role of music therapy for patients in institutional facilities and community settings.
5. Assess the patient's need or desire for CAM therapies.
6. Incorporate appropriate CAM therapies into the patient's plan of care.
7. Evaluate patient outcomes when using CAM therapies.

OVERVIEW

Western biomedicine is the predominant health care system in the United States and other Western countries. However, during the past 30 years, a growing interest in **complementary** (together with traditional treatment) and **alternative** (in place of traditional treatment) medicine has rapidly evolved. **Complementary and alternative medicine (CAM)** is a diverse group of systems, practices, and products that are not an official part of today's U.S. traditional biomedical health care system. However, there is growing scientific evidence that some CAM therapies are as effective as traditional or conventional therapies. **Integrative medicine** combines therapies from traditional Western medicine and CAM. A growing number of health care systems have an integrated medicine or CAM department.

Most people who seek complementary and alternative therapies pay for them out-of-pocket because most third-party payers reimburse for only selected therapies such as chiropractic treatment and acupuncture. More women than

men and people with high formal educational levels are most likely to use CAM (National Center for Complementary and Alternative Medicine [NCCAM], 2008).

Unlike traditional medicine, CAM therapies are part of the **holistic care** movement—the connection and integration of the mind, body, and spirit. Four common alternative holistic systems practiced in the United States are homeopathic, naturopathic, Ayurvedic, and Traditional Chinese Medicine. Homeopathic and naturopathic medicine started in Germany in the 1800s and have been used in the United States for less than 100 years. Ayurvedic medicine originated in India over 3000 years ago and is gaining popularity in the United States. Traditional Chinese Medicine is the oldest medical system in the world and is commonly practiced in the United States today. Acupressure and acupuncture therapies are used most often; these therapies are described on p. 12 in this chapter.

Homeopaths plan individualized care by prescribing small doses of specially prepared plant and animal extracts and minerals to promote healing. **Naturopaths** are more

holistic in that they use a combination of physical therapies, herbal preparations, homeopathic remedies, acupuncture, and lifestyle changes to improve health. Both homeopaths and naturopaths complete specialized training and certification but are not recognized in all U.S. states. Practitioners of Ayurvedic medicine (also called *Ayurveda*) employ a variety of CAM therapies to eliminate impurities from the body, reduce symptoms, increase resistance to disease, and promote balance and harmony. Examples of therapies used for these purposes include meditation, massage, herbs, and exercise (NCCAM, 2011c).

Nurses and other health care providers believe in a holistic, caring approach to practice. Many CAM therapies do not require special or advanced training to use them with patients. Others, such as acupuncture, require specialized education and, in some states, licensure or certification. This chapter briefly *introduces* some of the common CAM therapies used by patients and nurses in a variety of settings. More detailed discussions of specific CAM usage for selected health problems and associated nursing implications are found throughout this text in sections labeled with the heading “Complementary and Alternative Therapies.” Medical-surgical nurses play a key role in assessing the need for CAM and teaching patients and their families about how to safely use CAM therapies.

NATIONAL CENTER FOR COMPLEMENTARY AND ALTERNATIVE MEDICINE

As a result of growing interest in CAM, the National Institutes of Health established the *National Center for Complementary and Alternative Medicine* (NCCAM). The purposes of this center are to:

- Fund studies examining the effectiveness of various complementary therapies
- Advance the knowledge about complementary therapies of health professionals
- Serve as a clearinghouse for information about these therapies

NCCAM classifies complementary and alternative medicine into four major categories, as summarized in Table 2-1. These categories include:

- Natural products
- Mind-body therapies
- Manipulative and body-based therapies
- Other CAM modalities, such as energy and cognitive-behavioral therapies

CAM CATEGORIES

Natural Products

Most natural products are either nutraceuticals (dietary and herbal supplements) or probiotics. As a group, these products are thought to provide health and medical benefits and are used widely, especially by older adults (Zarowitz, 2010). In the United States, *nutraceuticals* and *probiotics* are regulated as food and nutritional supplements by the Food and Drug Administration (FDA). However, these regulations are less strict than those for drug therapy, which has raised increasing concern about their safety. Dietary and herbal supplements do not receive the same stringent oversight in their preparation and use as drugs. Therefore they cause a

TABLE 2-1 NCCAM CATEGORIES OF CAM WITH EXAMPLES

DOMAIN	EXAMPLES
Natural products	Nutraceuticals (dietary supplements), such as calcium and magnesium; probiotics, including foods (e.g., yogurt) and supplements (e.g., <i>Lactobacillus</i>)
Mind-body therapies	Imagery, meditation, music, humor, biofeedback, yoga, prayer, pet therapy
Manipulative and body-based therapies	Chiropractic treatment, massage, tai chi
Other CAM therapies	Healing Touch, Therapeutic Touch, Reiki

CAM, Complementary and alternative medicine; NCCAM, National Center for Complementary and Alternative Medicine.

range of patient responses depending on their nature and how they were prepared. Herbal preparations that are sold as standardized extracts are more likely to contain larger amounts of the herb or nutritional element and less likely to contain inactive ingredients or fillers. *Teach patients that because an herb is labeled as “natural,” it does not mean that the herb is safe. Because it may be safe does not mean that it is effective.*

Some dietary and herbal supplements have pharmacologic effects that can be serious or deadly, as in cases of overuse, inappropriate use, supplement toxicities, and supplement-drug and supplement-supplement interactions.

CONSIDERATIONS FOR OLDER ADULTS

Older adults in the community often overuse dietary and herbal supplements to help prevent potentially life-threatening health problems and promote quality of life. For example, older women may take too much calcium because they want to prevent osteoporosis. As a result, excess calcium can deposit in kidneys as renal calculi (stones). Teach women the importance of collaborating with their health care provider to monitor serum calcium levels and kidney function before and during calcium supplementation.

Older adults who live in independent and assisted-living communities often self-administer a variety of supplements without telling their nurses or primary care providers. Nurses working in these settings need to talk with their residents about the safety and efficacy of CAM therapies. To prevent toxicities and supplement-drug interactions, encourage residents to inform the health care team about which supplements they are taking (Moquin et al., 2009).

In some cases, herbal preparations are self-administered to treat a serious health problem that could more effectively be treated by conventional medicine, potentially resulting in a delay of diagnosis and treatment. For example, patients may take St. John’s wort for depression rather than be evaluated for possible psychotherapy and/or drug therapy. In other cases, patients may neglect or choose not to tell their health care providers about their use of supplements. As a result, they may take conventional drugs and natural products to treat the same condition. The resulting drug-supplement interactions may be harmful or life threatening.

Caution patients about unreliable sources of health information, and refer them to credible resources for herbal remedies. Examples of excellent websites for accurate information

! NURSING SAFETY PRIORITY

Drug Alert

When caring for patients in any health care setting, ask them if they use herbs or nutritional supplements and, if so, for what purpose. Ask about the frequency and dose of the products used. To prevent complications, remind patients of the importance of telling all health care providers about dietary supplement or herbal therapy use. For example, to avoid increased risks of bleeding, one should not use ginkgo, ginseng, or garlic for at least 3 days before surgery. Table 2-2 lists several commonly used herbs, their uses, and their precautions. Teach patients about these precautions and how to safely use them.

are the Herb Research Foundation (www.herbs.org) and The National Center for Complementary and Alternative Medicine (www.nccam.nih.gov).

Probiotics, another commonly used group of products, are live microorganisms that are similar to those naturally found in the GI tract. When taken orally, these organisms colonize to enhance the immune response and stabilize the GI mucosal barrier. Most probiotics are bacteria that come from two groups—*Lactobacillus* and *Bifidobacterium*. Within each of these main groups are different species or strains. A few probiotics are yeasts.

Probiotics are available in foods and dietary supplements. Examples of foods containing probiotics are yogurt, miso, tempeh, and some soy and juice beverages. Dietary supplements include capsules, tablets, and powders. Patients use probiotics to treat antibiotic-associated diarrhea (AAD), irritable bowel syndrome, bladder and intestinal infections, and lactose intolerance (NCCAM, 2011e).

Research on the effectiveness of probiotics has been promising but sometimes conflicting. A recent meta-analysis of 10 randomized controlled trials on the role of *Lactobacillus* to prevent AAD reported that the risk for developing AAD was significantly lower when probiotics were compared with placebo usage (Kale-Pradhan et al., 2010). Additional studies are underway to determine the safety and effectiveness of other probiotic types and strains (Zarowitz, 2010).

Teach patients that side effects of probiotics include gas and bloating. Remind them to take the product with meals. As always, tell patients to check with their health care providers before taking these products and inform future providers that probiotics are being used.

Aromatherapy also uses natural products; it is one of the fastest growing complementary therapies. Clinical **aromatherapy** uses essential oils from various parts of plants and trees to enhance psychological and physical well-being. Essential oils may be applied in compresses, used in baths, or applied topically to the skin to stimulate the brain to decrease pain, improve mood, or enhance cognitive function.

Numerous oils can be used. For example, lavender and rose are two common oils that promote relaxation and sleep. Peppermint has been used for stimulation and to promote concentration. Sandalwood, jasmine, and lavender may improve mood in patients with depression (NCCAM, 2011b). *Before using aromatherapy, assess the patient for any allergies and any negative associations with particular smells.* Some aromas can cause nausea and vomiting. Essential oils are potent and need to be diluted before being applied topically.

? NCLEX EXAMINATION CHALLENGE

Health Promotion and Maintenance

Which statement by a client about herbal supplements indicates a need for further teaching by the nurse?

- A. "I only take my herbs as instructed on the label of the containers."
- B. "I'll tell my doctor that I'm on these herbs after I see if they work."
- C. "I will report any new side effects that I get from taking these herbs."
- D. "I will continue taking the medicine that was prescribed by my doctor."

Mind-Body Therapies

Mind-body therapies are the most commonly used category of CAM. Because they are thought to enhance the mind's ability to affect body function, they fit with the holistic, caring philosophy of nursing. Nurses have traditionally used a number of mind-body therapies such as prayer, imagery, meditation, music, and pet therapy. *Prayer is the most commonly used mind-body therapy by health care professionals and patients with a variety of health care problems.* Chapter 4 discusses this practice as part of spiritual well-being.

Other mind-body therapies include yoga, acupuncture, and acupressure. The latter two techniques are provided

TABLE 2-2 COMMONLY USED HERBAL PREPARATIONS: DESIRED EFFECTS AND PRECAUTIONS

HERB	DESIRED EFFECTS/USES	HEALTH TEACHING/PRECAUTIONS
<i>Ginkgo biloba</i>	Reduces memory problems, dementia, peripheral vascular disease; has antioxidant and vasodilator properties.	Use with anticoagulants may cause bleeding; rarely dizziness, headache, GI upset.
Garlic	Lowers cholesterol or blood pressure; acts as a natural antibiotic; acts as an antiplatelet agent.	Bleeding can occur when used with other antiplatelet agents; potentiates action of antidiabetic drugs; avoid several days before surgery.
Glucosamine sulfate	Decreases inflammation; effective for knee osteoarthritic pain.	Takes several weeks to be effective; monitor for increased INR in patients taking warfarin; can cause GI upset—take with meals.
Ginseng	Promotes general well-being; anti-aging.	Observe INR with warfarin. Side effects depend on type of ginseng used.
Saw palmetto	Decreases prostatic hyperplasia.	Discontinue 2 weeks before surgery because it inhibits platelet aggregation (clotting).

INR, International normalized ratio.

by practitioners who have many years of education and experience.

Imagery

Imagery has been used for many years in nursing. **Imagery** is the formation of a mental representation of an object, place, event, or situation that is perceived through the patient's senses. Visualization is sometimes used interchangeably with imagery, but in reality, all senses can be used in imagery. Incorporate imagery techniques into the patient's plan of care as needed. For example, while changing dressings or doing other procedures that may produce pain, ask the patient to think about a beautiful scene or smelling fragrant flowers.

Imagery has been used for a wide variety of reasons, including:

- Reducing pain
- Reducing nausea and vomiting
- Decreasing anxiety
- Promoting comfort during treatment for cancer

Many techniques can be used to help people use their senses to create images. **Guided imagery** in which the patient is provided with images or prompts by a nurse, a family member, or a friend or via a tape is a technique frequently used by nurses. Before suggestions for imagery are presented, provide the patient with instructions that will help produce relaxation. These may include tensing and relaxing muscle groups and focusing attention on one's breathing, a technique called *progressive muscle relaxation*.

When the person seems relaxed (slower respirations and relaxed muscles), give specific suggestions for imagery. The patient may be asked to choose a place he or she enjoys and to think about the sights, smells, tastes, and feelings associated with the place. Time allowed for imagery varies but usually lasts between 15 and 20 minutes. Opportunities are provided for the person to enjoy being in this place; tell the patient that he or she can return to this "place" at any time. Some patients like to create their own imagery tape to listen to, whereas others prefer listening to commercial tapes or having the nurse or family member guide them through the session. Use of guided imagery has few risks. However, be attentive to any adverse effects such as heightened anxiety or difficulty in breathing.

Meditation

Meditation has been a part of many religions and cultures for thousands of years. Although often thought of in terms of religion, meditation, or focusing on the moment, can be used in a nonreligious context. Meditation has been used to reduce anxiety, reduce pain, relieve symptoms of psoriasis, lower blood pressure, and promote health (NCCAM, 2011d) (Fig. 2-1). Teach patients with these problems about the successful use of this therapy. Teach patients about resources that can help them learn how to use meditation.

Meditation is a self-directed practice for relaxing the body and mind. Some of the most common types of meditation are:

- Mental repetition such as using a mantra
- Physical repetition such as focusing on breathing or walking
- Problem contemplation such as solving a riddle
- Visual concentration that is similar to imagery

FIG. 2-1 Meditation can be used to relax the body and calm the mind.

Walking meditation, a commonly used type, contains both active and meditative elements. While walking, the person focuses attention on the sound of the foot hitting the ground, the feelings in the muscles and joints, or the movements of the body. This type of meditation may be appealing to persons who are more active and have difficulty concentrating while sitting. The walking meditation should be done for about 20 minutes.

The labyrinth is an ancient form of walking meditation that has attracted renewed attention. Labyrinths are found in many cultures such as Hindu, Hopi Indian, Crete, and medieval European religions. The labyrinth is not a maze. The person walks the circles meditatively. Walkers may ask themselves a question and search for answers, they may pray, or they might focus on feelings they are experiencing.

Music Therapy

Music therapy has been part of CAM for many years. Nursing homes and other long-term care settings commonly enjoy music as an important part of their activity program. Music often calms agitated patients and provides reminiscence for older adults, particularly when familiar music is played during meals (Wall & Duffy, 2010). It may also improve depression and lower blood pressure (Chan et al., 2009) and help reduce postoperative abdominal pain during the first 24 hours after surgery (Good et al., 2010) (see the Evidence-Based Practice box on p. 12).

A large systematic review of the literature conducted by Richards et al. (2007) found that music therapy decreased pain and anxiety in the hospital setting. It also showed that patients were more satisfied with their care when music therapy was provided. Results were better when an individual patient listened to calming live music such as that provided by a harp, when compared with listening to recorded music and other instruments.

Assess whether the patient wants to hear music. Be sure to provide music that is generation-appropriate and ask the patient or family what type of music is preferred. To promote relaxation, use calming music rather than music with a fast tempo.

Pet Therapy

It is not unusual to see dogs, cats, or other animals when visiting a hospital or nursing home. Since the 1970s, studies

EVIDENCE-BASED PRACTICE

Relaxation and Music for Postoperative Pain Compared with Pain Management Teaching

Good, M., Albert, J.M., Anderson, G.C., Wotman, S., Cong, X., Lane, D., et al. (2010). Supplementing relaxation and music for pain after surgery. *Nursing Research*, 59(4), 259-269.

Most patients having abdominal surgery experience unrelieved pain despite the use of patient-controlled analgesia (PCA). The researchers randomized 517 patients ages 18 to 75 years having abdominal surgery with PCA into four groups: pain management teaching only (PT), relaxation and music (RM), a combination of teaching and relaxation and music (PTRM), and a control group. Effects of pain were measured using visual analog sensation and distress scales during the first 2 days.

Using multivariate analysis of covariance with contrasts and pretest control, the two groups who had RM experienced pain reduction immediately after surgery. Surprisingly, pain management teaching had no effect on pain control. The researchers concluded that relaxation and music play an important role in pain control for postoperative abdominal patients during the first 2 days after surgery.

Level of Evidence: 2

This study used a randomized control design for a large number of patients. Randomization is an appropriate method for answering the research question.

Commentary: Implications for Practice and Research

The findings of this study demonstrate the value of CAM therapies in pain management for patients who typically cannot achieve pain control after abdominal surgery. Nurses are in an ideal position to implement CAM therapies such as music and relaxation techniques. More research needs to be conducted on other therapies to increase their use in hospitals and other health care settings.

have sought to validate the link between animal companionship and positive health outcomes. Pet therapy includes both animal-assisted therapy (AAT) and pet visitation. In AAT, the animal (often a dog) is an integral part of the treatment plan. For example, a dog may be used to assist a patient to improve motor skills or increase ability to concentrate.

In contrast, the purpose of pet visitation is aimed more at increasing socialization or keeping the person in touch with reality. Residents in assisted-living and long-term care facilities enjoy visiting with gentle, quiet pets, especially large, non-intimidating dogs. Collaborate with the activity therapist to include pet therapy for residents on a regular basis.

Pet therapy has been used with many different patient groups including hospice and behavioral health problems. It may be used in an institutional facility or in the community. Facilities that plan to implement pet therapy should first develop guidelines that specify the inclusion and exclusion criteria for patients who might receive it, the procedure to be used during the visitation, and the responsibilities of the nursing staff.

Some facilities also have pets or fish that live there. For example, a dog or cat may be “adopted” by residents in a nursing home or assisted-living facility. Many institutions have large aquariums in their lobby or other common area to enjoy a variety of fish or other sea life. Watching the activity within the aquarium can be very relaxing and therapeutic for some patients.

FIG. 2-2 Yoga can reduce stress and improve posture.

Yoga

Yoga is a popular mind-body therapy used around the world. An estimated 11 million people in the United States practice yoga to improve their breathing and posture through stretching, positioning, and posturing exercises (Fig. 2-2). Studies conducted throughout the world show that yoga also helps decrease blood pressure, increase heart and respiratory function, improve physical fitness, and decrease anxiety. It also is used as an adjunct in management of patients with multiple sclerosis, rheumatoid arthritis, and other chronic, potentially debilitating diseases (NCCAM, 2011f).

**NURSING SAFETY PRIORITY****Action Alert**

Teach patients to check with their health care provider before starting yoga because it can be very strenuous. Encourage older adults to take a course that is designed for people older than 60 years. Inform them about community resources for yoga classes or DVDs that can be used at home for yoga practice.

Acupressure and Acupuncture

Acupressure, a Traditional Chinese Medicine therapy, is used in health care for a number of conditions, particularly in the treatment of pain, nausea, and vomiting. **Acupressure** is an ancient healing art that uses the fingers to press certain points on the body to stimulate the body's self-healing ability. According to the philosophy of Traditional Chinese Medicine, *qi* or energy flows along 12 major meridians. Symptoms like pain occur when the flow of *qi* is blocked or diminished. Therefore the purpose of acupressure is to improve energy flow and decrease symptoms.

The philosophy of acupuncture is similar to acupressure. For **acupuncture**, very small needles are inserted on one of the 365 to 700 **acupoints** that are located on meridians throughout the body to release the flow of *qi*. This therapy is one of the oldest healing methods in the world. It has been shown to be effective in managing a number of health problems, including urinary incontinence, back pain, joint pain, and post-traumatic stress disorder (Engberg et al., 2009; NCCAM, 2011a). Some patients have been able to stop the habit of smoking by using acupuncture.

NCLEX EXAMINATION CHALLENGE

Health Promotion and Maintenance

An 80-year-old adult with severe back pain from osteoarthritis tells the nurse that she wants to participate in complementary and alternative therapies. Which therapies will the nurse recommend for this client? **Select all that apply.**

- A. Back massage
- B. Imagery
- C. Glucosamine
- D. Meditation
- E. Yoga

Manipulative and Body-Based Therapies

Three large groups of therapies make up the manipulative and body-based NCCAM category: chiropractic, osteopathy, and massage. Chiropractic and osteopathic medicine require years of specialized training. Massage and tai chi are common manipulative and body-based therapies that nurses can learn and teach to their patients.

Massage

Massage has a long history within nursing. Until recently, back rubs were a standard nursing procedure provided for all hospitalized patients on a daily basis. **Massage** involves using various strokes and pressure to manipulate soft tissues for therapeutic purposes. Many types of massage exist: Swedish (rather vigorous massage with long, flowing strokes), Esalen (light touch), neuromuscular (deep tissue), Shiatsu (Japanese pressure-point), and reflexology (massage of various points on the foot). Massage can be of the entire body or of selected areas such as foot, hand, shoulder/neck, or back (Fig. 2-3). Specialized licensed therapists use various types of massage in both health care and non-health care settings.

Massage can be used to produce relaxation and help lessen aggressive behaviors in patients with dementia (Holliday-Welsh et al., 2009). It may also reduce pain and blood pressure in some patients (Albert et al., 2009).

NURSING SAFETY PRIORITY

Action Alert

Because of cultural differences related to touch and personal preferences related to touch, be sure to obtain the patient's permission before using massage. Do not massage over reddened, bruised, or infected areas of skin.

Tai Chi

Tai chi is a holistic movement therapy that has wide popularity in China, Taiwan, and Japan. It is a traditional Chinese martial art that has been adapted to be a mind-body exercise. The purpose is to integrate body movements, mind concentration, muscle relaxation, and breathing to achieve the desired outcome. Several styles of tai chi exist: *chen* (quick and slow large movements), *yang* (slow large movements), *sun* (quick compact), and tai chi *chih* (simple repetitive movements). The latter is a style that is popular in the United States and Canada and originated in the West. Like other Traditional Chinese Medicine, tai chi promotes

FIG. 2-3 Massage therapy can be effectively used to relieve tension.

the flow of *qi* or energy throughout the body to reduce symptoms.

CONSIDERATIONS FOR OLDER ADULTS

Tai chi has been used successfully with older adults in community and health care settings. For example, Tsai et al. (2009) found that knee osteoarthritic pain decreased when cognitively impaired older adults practiced tai chi on a regular basis. In their study of residents living in a long-term care (LTC) facility, Lee et al. (2009) found that those who participated in the tai chi program had significant improvements in both the physical and mental components of the Health-Related Quality of Life assessment tool. The researchers recommended that tai chi exercise be offered regularly to LTC residents to improve their quality of life.

Other CAM Therapies

Energy therapies include both biofield therapies and bioelectromagnetics. They are based on the belief that the body has a subtle energy that extends beyond it. In nursing, biofield therapies are most commonly used. Examples include Therapeutic Touch (TT) and Reiki. Therapeutic Touch, *the most well-known energy therapy*, was developed by Dolores Krieger, a U.S. nurse, in the 1970s. Reiki is a Japanese spiritual healing therapy that has been used for almost 100 years. Both of these therapies can be learned and used by nurses in a variety of settings.

Therapeutic Touch is based on the assumption that illness is an imbalance in the flow of energy or the energy pattern within the body. Using TT, the practitioner intervenes in the patient's energy field to stimulate healing potential. This therapy has been used to achieve numerous health outcomes: reduced anxiety, decreased pain, improved immune system, and improved functional ability.

TT consists of five steps: centering, assessing the energy field, clearing and mobilizing the patient's energy field, directing energy for healing, and balancing the energy field. In centering, the practitioner is quiet and focuses attention on the patient with the intention to heal. The practitioner uses his or her hands to assess the flow of energy. They are then moved from head to foot, noting any blockages in the flow of energy or absences or excesses in energy in a particular spot. In the clearing and mobilizing step, the practitioner holds his or her hands 2 to 4 inches from the patient's body

FIG. 2-4 In Therapeutic Touch, the practitioner directs her own interpersonal energy to help or heal another.

and moves them with the palms facing the patient, from head to foot in a sweeping motion (Fig. 2-4). This process may be repeated. Based on the assessment, the practitioner directs energy so that imbalances are resolved. The practitioner's hands are placed on the patient, and energy is directed toward him or her. Finally, the practitioner seeks to balance the patient's energy by using head-to-toe clearing motions with the intention of smoothing the energy.

Reiki is also a healing therapy in which the healer uses 12 to 15 positions while holding his or her hands over the patient's body to decrease stress and promote relaxation. Both the healer and patient may feel warmth, coolness, and/or tingling as energy flows throughout the patient's body.

! NURSING SAFETY PRIORITY

Action Alert

Be aware that some patients experience dizziness and nausea during the energy therapy session. For that reason, use with caution in older adults and monitor them carefully during the therapy.

? DECISION-MAKING CHALLENGE

Evidence-Based Practice

A patient with liver cancer is experiencing increased pain and wants to supplement his drug therapy to prevent sedation and decreased alertness. He continues to go into the office where he works every day as a manager of a large clothing store. He tells you as his office nurse that it is getting harder to concentrate as his opioid doses increase.

1. Based on current evidence, what CAM therapies do you think would be best for the patient at this time and why?
2. What tools and resources did you use to answer Question 1?
3. How will you evaluate whether CAM therapies have been effective for this patient?

GET READY FOR THE NCLEX® EXAMINATION!

KEY POINTS

Review these Key Points for each NCLEX Examination Client Needs Category.

Health Promotion and Maintenance

- Teach patients taking herbal preparations about their uses, toxicities, herb-herb interactions, and herb-drug interactions (see Table 2-2).
- Teach patients about the value of probiotics and expected side effects.
- Teach patients the importance of telling their health care provider about the desire to use CAM therapies; remind them to inform future providers that therapies are being used.
- Use caution when using CAM therapies for older adults.

Physiological Integrity

- Complementary and alternative therapies include a broad range of healing approaches and therapies that are becoming more widely used in the United States. Many of these therapies are derived from Eastern medicine, such as Traditional Chinese Medicine (e.g., acupuncture).

- As part of the National Institutes of Health, the National Center for Complementary and Alternative Medicine (NCCAM) is funding research to determine the usefulness of selected therapies.
- The four major categories of CAM as specified by the NCCAM are listed with examples in Table 2-1.
- Include CAM therapies in the patient's plan of care as needed, especially those classified as mind-body therapies.
- Examples of mind-body therapies are prayer, imagery, meditation, music therapy, and pet therapy.
- Imagery is often used for reducing pain, nausea and vomiting, and anxiety.
- Massage is a commonly used manipulative and body-based therapy in nursing; do not massage over reddened or infected skin areas.
- Therapeutic Touch promotes healing by balancing a person's energy field.
- Evaluate whether CAM therapies are effective for patients in a variety of settings.

Common Health Problems of Older Adults

Key Points
Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Recognize the benefits of interdisciplinary health care team collaboration in the care of older adults.
2. Identify risk factors for falls and driving ability in older adults who live in the community or are hospitalized.
3. Explain falls risk and prevention interventions for older adults in the hospital and community.
4. Describe best practices to promote patient safety when using restraints.

Health Promotion and Maintenance

5. Teach selected evidence-based lifestyle practices to promote healthy activities in older adults.
6. Conduct a medication assessment for potential risks for adverse drug events in older adults.
7. Teach older adults about safe medication administration.

Psychosocial Integrity

8. Assess the older patient's risk for and signs of neglect and abuse.
9. Use valid and reliable tools to assess for mental/behavioral health problems in the older adult.
10. Compare characteristics of depression, delirium, and dementia.
11. Develop a plan of care to assist the older adult to cope with relocation stress syndrome.

Physiological Integrity

12. Identify four subgroups of older adults.
13. Explain factors that contribute to nutrition-related problems among older adults in the community and inpatient facilities.
14. Describe the effects of drugs on the older adult.
15. Assess for adverse drug effects of psychoactive drugs when taken by older adults.

About 13% of the people in the United States are older than 65 years. Women live longer than men, although the exact reason for this difference is not known. The older population is expected to grow as more “baby boomers” approach late adulthood during this decade. Most patients on adult acute care units are older than 65 years; many of these patients are discharged for home health services. Over 90% of patients in long-term care (LTC) facilities are older than 65 years. Therefore nurses and other health care professionals need to know about the special needs of older adults to care for them in a variety of settings.

This chapter describes the major health issues associated with late adulthood in community and inpatient settings. The

care of older adults (sometimes referred to as *elders*) with specific acute and chronic health problems is discussed as appropriate throughout this text. Nursing Focus on the Older Adult charts and Considerations for Older Adults headings highlight the most important information. A brief review of major physiologic changes of aging are listed in the Assessment chapter of each body system unit.

OVERVIEW

Late adulthood can be divided into four subgroups:

- 65 to 74 years of age: the young old
- 75 to 84 years of age: the middle old

- 85 to 99 years of age: the old old
- 100 years of age or older: the elite old

The fastest growing subgroup is the old old, sometimes referred to as the advanced older adult population. Members of this subgroup are sometimes referred to as the “frail elderly,” although a number of 85 to 95 year olds are very healthy and do not meet the criteria for being frail. Frailty is a clinical syndrome in which the older adult has unintentional weight loss, weakness and exhaustion, and slowed physical activity, including walking. Frail older adults are also at high risk for adverse outcomes (Rocchiccioli & Sanford, 2009).

The vast majority of older adults live in the community at home, in assisted-living facilities, or in retirement or independent living complexes. Men older than 65 years are less likely to live alone than women of that age. Of all older adults, 5% reside in LTC facilities (mostly nursing homes) and another 10% to 15% are ill but are cared for at home. Older adults from any setting usually experience one or more hospitalizations in their lifetime. About half of all older adults will be admitted at some time during their life for short-term stays in a skilled unit of a LTC facility, usually for rehabilitation or complex medical-surgical follow-up care.

Other institutions also have an increase in aging adults. For example, men older than 50 years are the fastest growing group of prisoners today. Like the rest of the older population, older prisoners have multiple chronic health problems. However, these problems are complicated by a history of alcohol and substance abuse and poor nutrition that require deliberate management strategies. Nurses who work in these settings need to develop expertise in care of older adults.

The number of homeless people older than 60 years is also growing. The inability to pay for housing and family/partner relationship problems are primary factors that contribute to this trend. Most homeless adults have one or more chronic health problems, including mental/behavioral health disorders. [Chapter 4](#) discusses issues related to the homeless population in more detail.

HEALTH ISSUES FOR OLDER ADULTS IN COMMUNITY-BASED SETTINGS

Health is a major concern for many older adults. Health status can affect the ability to perform ADLs and to participate in social roles. A failure to perform these activities may increase dependence on others and may have a negative effect on morale and life satisfaction. When older adults lose the ability to function independently, they often feel empty and worthless. Loss of autonomy is a painful event related to the physical and mental changes of aging.

Older adults may also experience a number of losses that can affect a sense of control over their lives, such as the death of a spouse and friends or the loss of social and work roles. Nurses need to support their self-esteem and feelings of independence by encouraging them to maintain as much control as possible over their lives, to participate in decision making, and to perform as many tasks as possible.

Like younger and middle-aged adults, older adults need to practice health promotion and illness prevention to maintain or achieve a high level of wellness. Teach them the importance of promoting wellness and strategies for meeting this outcome ([Chart 3-1](#)).

CHART 3-1 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Lifestyles and Practices to Promote Wellness

Health-Protecting Behaviors

- Have yearly influenza vaccinations (after October 1).
- Obtain a pneumococcal vaccination. (A routine revaccination may be necessary.)
- Have a tetanus immunization, and get a booster every 10 years.
- Wear seat belts when you are in an automobile.
- Use alcohol in moderation or not at all.
- Avoid smoking; if you do smoke, do not smoke in bed.
- Install and maintain working smoke detectors and/or sprinklers.
- Create a hazard-free environment to prevent falls; eliminate hazards such as scatter rugs and waxed floors.
- Use medications, herbs, and nutritional supplements according to your health care provider's prescription.
- Avoid over-the-counter medications unless your physician directs you to use them.

Health-Enhancing Behaviors

- Have a yearly physical examination; see your health care provider more often if health problems occur.
- Reduce dietary fat to not more than 30% of calories; saturated fat should provide less than 10% of your calories.
- Increase your dietary intake of complex carbohydrate and fiber-containing food to five or more servings of fruits and vegetables and six or more servings of grain products daily.
- Increase calcium intake to between 1000 and 1500 mg daily; take a vitamin D supplement every day if not exposed daily to sunlight.
- Allow at least 10 to 15 minutes of sun exposure two or three times weekly for vitamin D intake; avoid prolonged sun exposure.
- Exercise regularly three to five times a week.
- Manage stress through coping mechanisms that have been successful in the past.
- Get together with people in different settings to socialize.
- Reminisce about your life through reflective discussions or journaling.

Common health issues and problems that often affect older adults in the community include:

- Decreased nutrition and hydration
- Decreased mobility
- Stress and loss
- Accidents
- Drug use and misuse
- Mental health/behavioral health problems (including substance abuse)
- Elder neglect and abuse

Decreased Nutrition and Hydration

The minimum nutritional requirements of the human body remain consistent from youth through old age, with a few exceptions. Older adults need an increased dietary intake of calcium, vitamin D, vitamin C, and vitamin A because aging changes disrupt the ability to store, use, and absorb these substances. A sedentary lifestyle and reduced metabolic rate require a reduction in total caloric intake to maintain an ideal body weight. Malnutrition or nutrition-related problems can occur in older adults when these needs are not met.

Many physical aging changes influence nutritional status or the ability to consume needed nutrients. Diminished

senses of taste and smell often result in a loss of desire for food. Older adults have less ability to taste sweet and salt than to taste bitter and sour. This aging change may result in an overuse of table sugar and salt to compensate. Some older adults consume numerous desserts and other sweet foods, which can cause them to become overweight or obese. Teach older adults how to balance their diets with healthy food selections. Remind them to substitute herbs and spices to season food and vary the textures of food substances to feel satisfied.

Tooth loss and poorly fitting dentures from inadequate dental care or calcium loss can also cause the older adult to avoid important nutritious foods. Unlike today, dental preventive programs were not readily available or stressed as being important when today's older adults were younger. Older people with dentition problems eat soft, high-calorie foods such as ice cream and mashed potatoes, which lack roughage and fiber. Unless the person carefully chooses more nutritious soft foods, vitamin deficiencies, constipation, and other problems can result. The extensive use of prescribed and over-the-counter (OTC) drugs, including herbal supplements, may affect appetite, food tolerances, and food absorption and use.

Reduced income, chronic disease, fatigue, and decreased ability to perform ADLs are other factors that contribute to inadequate nutrition among older adults. "Fast food" is often inexpensive and requires no preparation. However, it is usually high in fat, carbohydrates, and calories but lacking in healthy nutrients. Older adults can become overweight or obese when they consume a diet high in fast food.

Other older adults may reduce their intake of food to near-starvation levels, even with the availability of programs such as food stamps, food banks, and Meals on Wheels. Many senior centers and homeless shelters offer meals, as well as group social activities. The lack of transportation, the necessity of traveling to obtain such services, and the inability to carry large or heavy groceries prevent some older adults from taking advantage of food programs. Others are too proud to accept free services.

Inadequate nutrition may also be related to loneliness. Older adults may respond to loneliness, depression, and boredom by not eating, which can lead to under-nutrition. Many who live alone lose the incentive to prepare or eat balanced diets, especially if they do not "feel well." Men who live at home alone are especially at risk for not eating enough calories to maintain their weight. Other factors associated with under-eating include being hospitalized before starting home health care, having a primary care provider who is not a female family member, and having a low level of education (Volkert et al., 2010).

Today more baby boomers and older adults recognize that healthy diet and plenty of hydration improve health and help restore body tissues. As a result, the organic food industry is rapidly expanding as some individuals try to make the best possible food choices. Organic foods, though, are typically more expensive than non-organic foods, and some older adults cannot afford them. Organic foods are also not readily available in all parts of the country.

Some older adults are at risk for **geriatric failure to thrive (GFTT)**—a complex syndrome including under-nutrition, impaired physical functioning, depression, and cognitive impairment (Rocchiccioli & Sanford, 2009). However, drug

! NURSING SAFETY PRIORITY

Action Alert

Perform nutritional screening for older adults in the community who are at risk for inadequate nutrition—either under-nutrition or obesity. Ask the individual about unintentional weight loss or gain, eating habits, appetite, prescribed and over-the-counter drugs, and current health problems. Determine contributing factors for older adults who have or are at risk for poor nutrition, such as transportation issues or loneliness. Based on these data, develop and implement a plan of care in collaboration with appropriate members of the health care team. [Chapter 63](#) describes nutritional assessment and management of nutrition problems in detail.

therapy, chronic diseases, major losses, and poor socioeconomic status can cause these same health problems. Be sure to consider these factors when screening for GFTT. For those at risk for or who have GFTT, collaborate with the older adult and family to plan referral to his or her primary care provider for extensive evaluation. Early supportive intervention can help prevent advanced levels of deterioration.

People older than 65 years are also at risk for dehydration because they have less body water content than younger adults. In severe cases, they require emergency department visits or hospital stays.

! NURSING SAFETY PRIORITY

Action Alert

Older adults sometimes limit their fluid intake, especially in the evening, because of problems associated with mobility, prescribed diuretics, and urinary incontinence. *Teach older adults that fluid restrictions make them susceptible to dehydration and electrolyte imbalances (especially sodium and potassium) that can cause serious illness or death.*

Incontinence may actually increase because the urine becomes more concentrated and irritating to the bladder and urinary sphincter. Teach older adults the importance of drinking 6 to 8 glasses of water a day plus other fluids as desired. Remind them to avoid excessive caffeine and alcohol because they can cause dehydration. [Chapter 13](#) discusses fluid and electrolyte imbalances in detail.

Decreased Mobility

Exercise and activity are important for older adults as a means of promoting and maintaining health ([Fig. 3-1](#)). Physical activity can help keep the body in shape and maintain an optimal level of functioning. Regular exercise has many benefits for older adults in community-based settings. The advantages of maintaining appropriate levels of physical activity include:

- Decreased risk for falls
- Increased muscle strength and balance
- Increased mobility
- Increased sleep
- Reduced or maintained weight
- Improved sense of well-being and self-esteem
- Decreased depression symptoms
- Improved longevity
- Reduced risks for diabetes, coronary artery disease, and dementia

A study by Weeks et al. (2008) found that past life experience, life transitions, and future health concerns affect the participation of older adults in physical activity. For example,

FIG. 3-1 Exercise is important to older adults for health promotion and maintenance.

women who worked outside the home and/or reared multiple children stated that they did not have the time or energy to exercise when they were young. Others thought that their current health status prevented them from engaging in exercise. Some older adults worried that increasing their activity level might increase their risk for hip fracture or arthritis.

Weeks et al. (2008) also found that when compared with seniors living independently, nursing home residents had a very low level of physical activity. The researchers suggested that nursing home staff members need to be trained in how to promote resident exercise at least twice a week. Nurses who work in nursing homes must collaborate with physical and occupational therapists to plan this training and implement a regular exercise program.

Assess older adults in any setting regarding their history of exercise and any health concerns they may have. For independent older adults, remind them to check with their health care provider to implement a supervised plan for regular physical activity. Teach all older adults about the value of physical activity.

For people who are homebound, focus on functional fitness, such as performing ADLs. For those who are not homebound, teach the importance of other types of exercise. Resistance exercise, for example, maintains muscle mass. Aerobic exercise, like walking, improves strength and endurance. One of the best exercises is walking at least 30 minutes, three to five times a week. The person may walk for 30 continuous minutes or walk 3 times a day for 10 minutes. During the winter, indoor shopping centers and other public places can be used. In addition, many senior centers and community centers offer exercise programs for older adults.

Swimming is also recommended but does not offer the weight-bearing advantage of walking. Weight bearing helps build bone, an especially important advantage for older women to prevent osteoporosis (see [Chapter 53](#)). Teach older adults who have been sedentary to start their exercise programs slowly and gradually increase the frequency and duration of activity over time, under the direction of their health care provider.

NCLEX EXAMINATION CHALLENGE

Health Promotion and Maintenance

Which statement by an older adult regarding her diet indicates a need for further teaching by the nurse?

- A. "I need to eat more calories to help me keep warm this winter."
- B. "I plan to eat more dairy foods like milk and yogurt every day."
- C. "I'm going to have dinner with my friends more often."
- D. "I plan to eat more raw fruits and whole grain foods every day."

Stress and Loss

Stress can speed up the aging process over time, or it can lead to diseases that increase the rate of degeneration. It can also impair the reserve capacity of older adults and lessen their ability to respond and adapt to changes in their environment.

Although no period of the life cycle is free from stress, the later years can be a time of especially high risk. Frequent sources of stress for the older population include:

- Rapid environmental changes that require immediate reaction
- Changes in lifestyle resulting from retirement or physical incapacity
- Acute or chronic illness
- Loss of significant others
- Financial hardships
- Relocation

How people react to these stresses depends on their personal coping skills and support networks. The loss of roles experienced by older adults often limits the availability of external support networks. For instance, losses leave many older adults without friends for support and help. As a result, many must rely solely on their personal resources to maintain their mental health/behavioral health. A combination of poor physical health and social problems leaves older adults susceptible to stress overload, which can result in illness and premature death.

The ways in which people adapt to old age depend largely on the personality traits and coping strategies that have characterized them throughout their lives. Establishing and maintaining relationships with others throughout life is especially important to the older person's happiness. Even more important than having friends is the nature of the friendships. People who have close, intimate, stable relationships with others in whom they confide are more likely to cope with crisis.

Some older adults have chosen to return to work at least on a part-time basis to increase their income and socialize with other people. If an individual retired between the ages of 55 and 65 years and lives into his or her 80s, funds can deplete; additional income is needed to meet basic needs, including money for prescription drugs. Although U.S. government Medicare Part A pays for inpatient hospital care, older adults pay for Medicare Part B to reimburse for 80% of most outpatient services, Medicare Part D for prescription drugs, and often a private Medi-Gap insurance (like United or Blue Cross/Blue Shield) to cover the costs not paid for by Medicare. The premiums for these insurances are very expensive and still require that older adults pay out-of-pocket copayments for health care services and prescription drugs.

Fortunately, most older adults are relatively healthy and live in and own their own homes. Physical and/or mental health

CHART 3-2 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Minimizing the Effects of Relocation Stress in Older Adults

- Provide opportunities for the patient to assist in decision making.
- Carefully explain all procedures and routines to the patient before they occur.
- Ask the family or significant other to provide familiar or special keepsakes to keep at the patient's bedside (e.g., family picture, favorite hairbrush).
- Reorient the patient frequently to his or her location.
- Ask the patient about his or her expectations during hospitalization or assisted-living or nursing home stay.
- Encourage the patient's family and friends to visit often.
- Establish a trusting relationship with the patient as early as possible.
- Assess the patient's usual lifestyle and daily activities, including food likes and dislikes and preferred time for bathing.
- Avoid unnecessary room changes.
- If possible, have a family member, significant other, staff member, or volunteer accompany the patient when leaving the unit for special procedures or therapies.

problems may force some to relocate to a retirement center or an assisted-living facility, although these facilities can be very expensive. Others move in with family members or apartment buildings funded and designated for seniors. Older adults usually have more difficulty adjusting to major change when compared with younger and middle-aged adults. Being admitted to a hospital or nursing home is a particularly traumatic experience. Older adults often suffer from relocation stress syndrome, also known as *relocation trauma*. **Relocation stress syndrome** is the physical and emotional distress that occurs after the person moves from one setting to another. Examples of physiologic behaviors are sleep disturbance and increased physical symptoms, such as GI distress. Examples of emotional manifestations are withdrawal, anxiety, anger, and depression. **Chart 3-2** lists nursing interventions that may help decrease the effects of relocation.

Family members and facility staff need to be aware that older adults need personal space in their new surroundings. Older adults need to participate in deciding how the space will be arranged and what they can keep in their new home to help offset potential feelings of powerlessness. Suggest that the patient or family bring in personal items, such as pictures of relatives and friends, favorite clothing, and valued knick-knacks, to assist in making the new setting seem more familiar and comfortable. This same intervention can be carried out in a hospital setting.

Accidents

Accidents are very common among older adults; falls are the most common. Motor vehicle crashes increase as well because of physiologic changes of aging or chronic diseases like Alzheimer's or arthritis.

Fall Prevention

Most accidents occur at home. Teach older adults about the need to be aware of safety precautions to prevent accidents, such as falls. Incapacitating accidents are a primary cause of

decreased mobility and chronic pain in old age. Some people develop **fallopobia** (fear of falling) and avoid leaving their homes.

Home modifications may help prevent falls. Collaborate with family and significant others when recommending useful changes to prevent older adult injury. Safeguards such as handrails, slip-proof pads for rugs, and adequate lighting are essential in the home. Avoiding scatter rugs, slippery floors, and clutter is also important to prevent falls. Installing grab bars and using non-slip bathmats can help prevent falls in the bathroom. Raised toilet seats are also important. Remind older adults to avoid going out on days when steps are wet or icy and to ask for help when ambulating. To minimize sensory overload, advise the older adult to concentrate on one activity at a time.

Changes in vision, touch, and motor ability can create challenges for older adults in any environment. For example, **presbyopia** (farsightedness that worsens with aging) may make walking more difficult; the person is less aware of the location of each step. In addition, the older adult may have disorders that affect visual acuity, such as macular degeneration, cataracts, glaucoma, or diabetic retinopathy. Teach the person to look down at where he or she is walking and have frequent eye examinations to update glasses or contact lenses to improve vision. Drug therapy or surgery may be needed to correct glaucoma or cataracts.

A reduced sense of touch decreases the awareness of body orientation (e.g., whether the foot is squarely on the step). The decreased reaction time that commonly results from age-related changes in the neurologic system may also impair the ability to recognize or move from a dangerous setting. Chronic diseases can affect mobility and sensation in the older adult as well, such as peripheral neuropathy and arthritis. If needed, encourage the use of visual, hearing, or ambulatory assistive devices. High costs and a fear of appearing old sometimes prevent older adults from obtaining or using hearing aids, eyeglasses, walkers, or canes.

Once an older person has been identified as being at high risk for falls, choose interventions that help prevent falls and possible serious injury. For those in the community, tai chi exercise is very helpful to improve balance and functional mobility, as well as to decrease the fear of falling, especially among older women (Wooten, 2010). Tai chi is described in **Chapter 2**.

Driving Safety

Motor vehicle crashes are the most common cause of injury-related death in the young-old population, those between 65 and 74 years of age. Increased national concerns about this growing problem have prompted many states to require more frequent testing for older drivers. As one ages, reaction time and the ability to multitask decrease. Sleep disturbances, especially insomnia, are also common in older adults but are *not* part of normal aging. Some crashes occur because the person falls asleep while driving.

The older the person, the more likely he or she will have chronic diseases and the drugs needed to manage them. These health problems and treatments can contribute to motor vehicle crashes. For instance, drugs used for hypertension can cause orthostatic hypotension (low blood pressure when changing body position from a supine to sitting or standing position).

CHART 3-3 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Recommendations for Improving Older Driver Safety

- Discuss driving ability with the patient to assess his or her perception.
- Assess physical and mental deficits that could affect driving ability.
- Consult with appropriate health care providers to treat health problems that could interfere with driving.
- Suggest community-based transportation options, if available, instead of driving.
- Discuss driving concerns with patients and their families.
- Remind the patient to wear glasses and hearing aids, if prescribed.
- Encourage driver refresher classes, often offered by AARP (formerly the American Association of Retired Persons).
- Consult a certified driving specialist for an on-road driving assessment.
- Encourage avoiding high-risk driving locations or conditions, such as busy urban interstates and wet or icy weather conditions.
- Report unsafe drivers to the state department of motor vehicles if they continue to drive.

Physicians and other health care professionals play a major role in identifying driver safety issues. Yet, many are reluctant to intervene because older patients feel they will lose their independence if they cannot drive. They may also be angry and resistant to the idea of giving up perhaps their only means of transportation. As an alternative, health care professionals can recommend driving refresher courses and suggest that high-risk driving conditions, like wet roads, be avoided. Newer vehicles have some safety features to help older adults, such as large-print digital readouts for speed and other data. [Chart 3-3](#) lists additional ways to improve older adult driver safety.

Drug Use and Misuse

Drug therapy for the older population is another major health issue. Because of the multiple chronic and acute health problems that occur in this age-group, drugs for older adults account for about one third of all prescription drug costs. The term **polymedicine** has been used to describe the use of many drugs to treat multiple health problems for older adults. **Polypharmacy** is the use of multiple drugs, duplicative drug therapy, high-dosage medications, and drugs prescribed for too long a period of time (Planton & Edlund, 2010). In other words, polypharmacy occurs when there is inappropriate or unnecessary prescribing that results in negative outcomes.

Older adults commonly take multiple nonprescription (OTC) drugs, such as analgesics, antacids, cold and cough preparations, laxatives, and herbal/nutritional supplements, often without consulting a health care provider. Therefore this population is at high risk for adverse drug events (ADEs) directly related to the number of drugs taken and the frequency with which they are taken. Drug-drug, food-drug, drug-herb, and drug-disease interactions are common ADEs that often lead to hospital admission.

Effects of Drugs on Older Adults

Older adults often do not tolerate the standard dosage of drugs traditionally prescribed for younger adults. The physiologic changes related to aging make drug therapy more

complex and challenging. These changes affect the absorption, distribution, metabolism, and excretion of drugs from the body. Even common antibiotics can lead to temporary memory loss or acute confusion.

Age-related changes that can potentially affect drug *absorption* from an oral route include an increase in gastric pH, a decrease in gastric blood flow, and a decrease in GI motility. Despite these changes, older adults do not have major absorption difficulties because of age-related changes alone.

Age-related changes that affect drug *distribution* include smaller amounts of total body water, an increased ratio of adipose tissue to lean body mass, a decreased albumin level, and a decreased cardiac output. Increased adipose tissue in proportion to lean body mass can cause increased storage of lipid-soluble drugs. This leads to a decreased concentration of the drug in plasma but an increased concentration in tissue.

Drug *metabolism* often occurs in the liver. Age-related changes affecting metabolism include a decrease in liver size, a decrease in liver blood flow, and a decrease in serum liver enzyme activity. These changes can result in increased plasma concentrations of a drug. Monitor liver function studies, and teach older adults to have regular physical examinations.

Changes in the kidneys can also result in high plasma concentrations of drugs. The *excretion* of drugs usually involves the renal system. Age-related changes of the renal system include decreased renal blood flow and reduced glomerular filtration rate. These changes result in a decreased creatinine clearance and thus a slower excretion time for medications. Consequently, serum drug levels can become toxic and the patient can become extremely ill or die. Monitor renal studies, especially serum creatinine and creatinine clearance, when giving drugs to older adults.

A creatinine clearance test measures the glomerular filtration rate of the kidneys. A commonly used formula for calculating creatinine clearance for men rather than directly measuring it is:

$$\frac{(140 - \text{Age in years}) \times \text{Lean body weight in kg}}{\text{Serum creatinine in mg/dL} \times 72}$$

For women, use this formula and multiply the answer by 0.85. A normal creatinine clearance for men is 107 to 139 mL/min and for women is 87 to 107 mL/min. Values decrease by 6.5 mL/min for each decade of life after 20 years of age (Pagana & Pagana, 2010).

When chronic disease is added to the physiologic changes of aging, drug reactions have a more dramatic effect and take a longer time to correct. Often a lower dose of a drug is necessary to prevent ADEs. The policy of “start low, go slow” is essential when health care providers prescribe drugs for older adults. The physiologic changes of aging are highly individual. Alterations in drug therapy should always be individualized according to the actual physiologic changes present and the occurrence and severity of chronic disease. Common ADEs are listed in [Table 3-1](#).

Self-Administration of Drugs

Most people older than 65 years take their own medications. Because the risk for drug toxicity is considerably increased in the older population, assist patients in assuming this task responsibly. Teach patients and their caregivers, providing

TABLE 3-1 COMMON ADVERSE DRUG EVENTS (ADES) IN OLDER ADULTS

| • Fatigue | • Hypotension |
| • Weakness | • Acute confusion |

**FIG. 3-2** A medication system for safe self-administration.

clear and concise directions and developing ways to assist them in overcoming difficulties with self-administration.

Older adults may make errors in self-administration or do not adhere to the drug regimen for several reasons. First, they may simply forget. In the rush of daily activities, they may not take their drugs or may take them too often because they cannot remember when or whether they have taken the medications. It is often helpful if they associate pill taking with daily events (e.g., meals) or keep a simple chart or calendar. Pill boxes are available for a daily, weekly, or monthly supply of medicine that can be placed in small compartments (Fig. 3-2). Egg cartons can be very cost-effective pill boxes. Large print on the drug label assists patients who have poor vision. Writing the drug regimen on the top of the bottle with large letters and numbers is helpful for some older adults. Colored labels or dots can also be applied. Easy-open bottle caps help older adults with limited hand mobility or strength.

A second reason for drug errors is poor communication with health care professionals. These problems result from poor explanations that are not understood because of educational limitations, language barriers, or difficulty with hearing and vision. Health care professionals often presume that their patients have learned the information if they have taught them about the drugs. Assist older adults in planning their drug therapy schedules as needed.

A third reason for errors is the varying ways that patients take their medications. Some add to their drug regimen by taking over-the-counter (OTC) drugs, which can interact with prescription drugs and cause serious problems. For example, a patient receiving warfarin (Coumadin, Warfilone) for anticoagulation may take ibuprofen (Motrin) regularly for arthritis or garlic for hypertension. Because ibuprofen and garlic can inhibit clotting, this combination can cause serious bleeding. When obtaining a drug history, ask patients about all OTC drugs, including herbal and food supplements. Chapter 2 discusses herbal therapy in more detail.

TABLE 3-2 EXAMPLES OF BEERS CRITERIA FOR POTENTIALLY INAPPROPRIATE MEDICATION USE IN OLDER ADULTS

- | | |
|---|---|
| • meperidine (Demerol) | • promethazine (Phenergan) |
| • cyclobenzaprine (Flexeril) | • ketorolac (Toradol) |
| • digoxin (Lanoxin) (Should not exceed 0.125 mg daily except for atrial fibrillation) | • Short-acting nifedipine (e.g., Procardia) |
| • ticlopidine (Ticlid) | • ferrous sulfate (Iron) (Should not exceed 325 mg/day) |
| • fluoxetine (Prozac) | • chlorpropamide (Diabinese) |
| • amitriptyline (Elavil) | • diphenhydramine (Benadryl) |
| • diazepam (Valium) | |

Some other older adults avoid taking their prescribed drugs. The fear of dependency or the cost of the drugs may cause many to discontinue their drug therapy too soon or not begin taking the drug. In addition, the actions or side effects of some drugs may not be desirable. For example, diuretics may cause incontinence when patients cannot get to the bathroom quickly enough. Others may think that two pills are twice as effective and, therefore, better than taking just one. Some older adults take drugs that are leftover from a previous illness or one that is borrowed from someone else. Teach patients to take their medications exactly as prescribed by their health care providers.

Medication Assessment and Health Teaching

The Beers Criteria for Potentially Inappropriate Medication Use in Older Adults assessment tool, also known as the *Beers criteria*, is very useful in screening for medication-related risks in older adults who have chronic health problems (Molony, 2009). The tool lists multiple medications and related concerns. Examples of these “at-risk” drugs are listed in Table 3-2.

To reduce drug-related risks in older adults, perform a medication assessment every 6 months or more often if an acute illness or exacerbation of a chronic disease occurs. Be sure to:

- Obtain a list of all medications taken on a regular and as-needed basis; include OTC and prescribed drugs, herbs, and nutritional supplements. If a list is not available, ask the older adult or family to gather all ointments, pills, lotions, eyedrops, inhalers, injectable solutions, vitamins, minerals, and other OTC medications and place into a bag for review (Greenawalt, 2009).
- Highlight all medications that are part of the Beers criteria; highlight any medication where the indication for its use is not clear, inappropriate, or could be discontinued (e.g., duplicative drug).
- Collaborate with the older adult, family, pharmacist, and primary health care provider if appropriate to determine the need for medication changes. Suggest once-a-day dosing if possible.
- Give older adults verbal and written information (at the appropriate reading level) regarding any change or new medication prescribed.
- Promote adherence to the drug therapy regimen exactly as prescribed; remind older adults to check with their primary care provider if they want to change their

regimen or add an OTC medication or natural product (nutritional or herbal supplement, or probiotic).

- Encourage lifestyle changes and other nonpharmacologic interventions to help manage or prevent health problems.
- Remind older adults not to share or borrow medications.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

A community health nurse conducts an assessment of an older adult's medications. Which medication taken by the client every day has the highest risk for adverse drug events?

- A. Digoxin (Lanoxin) 0.375 mg
- B. Acetaminophen (Tylenol) 650 mg
- C. Furosemide (Lasix) 180 mg
- D. Amlodipine (Norvasc) 5 mg

Mental Health/Behavioral Health Problems

Older adults are usually mentally sound and competent. A few changes in cognition have been identified as age related and are linked to specific cognitive functions rather than intellectual capacity. These changes include a decreased reaction time to stimuli and an impaired memory for recent events. *However, severe cognitive impairment, depression, hallucinations, and delusions are not part of the normal aging process.*

Two forms of competence exist: legal competence and clinical competence. A person is **legally competent** if he or she is:

- 18 years of age or older
- Pregnant or a married minor
- A legally emancipated (free) minor who is self-supporting
- Not declared incompetent by a court of law

If a court determines that a person is not legally competent, a **guardian** is appointed to make health care decisions. Guardians may be family members or a person who is not related to the patient. When no one is available, a guardian may be appointed from a local Area Agency on Aging, an organization with services and resources for older adults.

A person is **clinically competent** if he or she is legally competent and can make clinical decisions. Decisional capacity is determined by a person's ability to identify problems, recognize options, make decisions, and provide the rationale supporting the decisions. Selected behavioral/mental illnesses often affect both legal and clinical competence.

Nurses are in a unique position to teach older adults about ways to promote cognitive health. In a recent systematic literature review, Williams and Kemper (2010) found that collaborative interventions targeting cognitive training (e.g., learning a new skill), physical activity, social engagement, and nutrition were the most helpful in optimizing cognitive aging.

As older adults age, they are at increasing risk for cognitive health problems—depression, delirium, and dementia, often referred to as the 3Ds. Many older veterans of the Korean and Vietnam wars also suffer from chronic pain, depression, post-traumatic stress disorder (PTSD), and severe anxiety. Substance abuse, especially alcoholism, is common among veterans and older adults in general. Alcoholism can

contribute to cognitive decline and may be used as a coping mechanism for loss. Several behavioral health problems are discussed briefly here; more comprehensive discussions can be found in mental health/behavioral health textbooks.

Depression

Depression is the most common mental health/behavioral health problem among older adults in the community, affecting 15 of every 100 older adults (National Institute of Mental Health, 2011). It increases in incidence when older adults are admitted to the hospital or nursing home. **Depression** is broadly defined as a mood disorder that can have cognitive, affective, and physical manifestations. It can be primary or secondary and can range from mild to severe, or major. As a *primary* problem, depression is thought to result from a lack of the neurotransmitters *norepinephrine* and *serotonin* in the brain. *Secondary* depression, sometimes called *situational* depression, can result when there is a sudden change in the person's life, such as an illness or loss. Common illnesses that can cause secondary depression include stroke, arthritis, and cardiac disease. It is often underdiagnosed by physicians and is therefore undertreated.

Families and nurses are in the best position to suspect depression in an older adult. Several screening tools are available to help determine if the patient has clinical depression. The **Geriatric Depression Scale—Short Form (GDS-SF)** is a valid and reliable screening tool and is available in multiple languages. The patient selects “yes” or “no” to 15 questions, or a nurse or other health care professional can ask the questions to the patient. A score of 10 or greater is consistent with a possible diagnosis of clinical depression (Fig. 3-3). These patients are then evaluated more thoroughly by the health care provider for treatment. Without diagnosis and treatment, depression can result in:

- Worsening of medical conditions
- Risk for physical illness
- Alcoholism and drug abuse
- Increased pain and disability
- Delayed recovery from illness
- Suicide

Older adults have the highest suicide rate of any age-group. Non-Hispanic white men who are 75 to 85 years of age are the most likely to die from suicide than any other older subgroup.

Older adults with depression may have early morning insomnia, excessive daytime sleeping, poor appetite, a lack of energy, and an unwillingness to participate in social and recreational activities. The primary treatment for depression usually includes drug therapy and psychotherapy.

Selective serotonin reuptake inhibitors (SSRIs) are the first choice for drug therapy but take 2 to 3 weeks to work. They act by increasing the amount of serotonin and norepinephrine at nerve synapses in the brain.

NURSING SAFETY PRIORITY

Drug Alert

Tricyclic antidepressants should not be used because they have anticholinergic properties that can cause acute confusion, severe constipation, and urinary incontinence. For older adults who may be prescribed this group of drugs, question the health care provider and request an SSRI or other treatment.

Geriatric Depression Scale—Short Form

Choose the best answer for how you have felt over the past week:

1. Are you basically satisfied with your life? YES / **NO**
2. Have you dropped many of your activities and interests? **YES** / NO
3. Do you feel that your life is empty? **YES** / NO
4. Do you often get bored? **YES** / NO
5. Are you in good spirits most of the time? YES / **NO**
6. Are you afraid that something bad is going to happen to you? **YES** / NO
7. Do you feel happy most of the time? YES / **NO**
8. Do you often feel helpless? **YES** / NO
9. Do you prefer to stay at home, rather than going out and doing new things? **YES** / NO
10. Do you feel you have more problems with memory than most? **YES** / NO
11. Do you think it is wonderful to be alive now? YES / **NO**
12. Do you feel pretty worthless the way you are now? **YES** / NO
13. Do you feel full of energy? YES / **NO**
14. Do you feel that your situation is hopeless? **YES** / NO
15. Do you think that most people are better off than you are? **YES** / NO

Answers in bold indicate depression. Score 1 point for each bolded answer.

A score > 5 points is suggestive of depression.

A score ≥ 10 points is almost always indicative of depression.

A score > 5 points should warrant a follow-up comprehensive assessment.

FIG. 3-3 The Geriatric Depression Scale—Short Form.

Recent research has demonstrated that reminiscence or reflective therapies also help older adults overcome feelings of depression and despair. A study by McCaffrey et al. (2010) determined that frequent walking through a large garden and reflective journaling decreased depression as measured by the Geriatric Depression Scale (see the Evidence-Based Practice box on p. 24). More information about depression, including strategies for preventing depression, is available in mental health/behavioral health nursing textbooks.

Dementia

Dementia is a broad term used for a syndrome that involves a slowly progressive cognitive decline, sometimes referred to as *chronic confusion*. This syndrome represents a global impairment of intellectual function and is generally chronic and progressive. There are many types of dementia, the most common being Alzheimer's disease. Multi-infarct dementia, the second most common dementia, is a vascular disorder and accounts for 20% to 25% of all dementias. [Chapter 44](#) discusses dementias in detail, with a focus on Alzheimer's disease.

Delirium

Whereas dementia is a chronic, progressive disorder, **delirium** is an *acute* state of confusion. Delirium also differs from dementia in that it is often short-term and reversible within

a month or less. It is often seen among older adults in a setting with which they are unfamiliar. It occurs in up to 50% of older adults who are hospitalized (Sendelbach & Guthrie, 2009). In addition to cognitive changes, some patients have physical and emotional manifestations. The types of delirium are *hyperactive*, *hypoactive*, *mixed*, and *unclassifiable*. *Hyperactive* patients may try to climb out of bed or become agitated, restless, and aggressive. *Hypoactive* patients are quiet, apathetic, and withdrawn. *Mixed* delirium patients have a combination of hyperactive and hypoactive manifestations. Others cannot be classified in one of these categories.

Some of the multiple factors that can cause delirium are:

- Drug therapy (especially anticholinergic and psychoactive drugs)
- Electrolyte imbalances
- Infections, especially urinary tract, pneumonia, and sepsis
- Fecal impaction or severe diarrhea
- Surgery
- Metabolic problems, such as hypoglycemia
- Neurologic disorders, such as tumors
- Circulatory, renal, and pulmonary disorders
- Nutritional deficiencies
- Hypoxia
- Relocation
- Major loss

EVIDENCE-BASED PRACTICE

Do Reflective Activities Improve Symptoms of Depression and Despair in Older Adults?

McCaffrey, R., Hanson, C., & McCaffrey, W. (2010). Garden walking for depression: A research report. *Holistic Nursing Practice*, 24(5), 252-259.

Depression affects 15 of every 100 older adults at some point in their later years, which leads to physical, mental, and social dysfunction. In this mixed-method design study, the researchers created a walking guide and reflective journal entitled *Stroll for Well-Being: Garden Walks at the Morikami Museum* (Stroll) to be used by 40 community-dwelling older adults at their convenience for 12 visits over a period of 6 months. The participants were either self-diagnosed or were being treated by a health care provider for depression. The sample was 62.5% white and 12.5% African American. The remaining group was a mix of ethnic backgrounds. Most participants were educated at a high school level or higher.

The *Stroll* was structured so that they would spend about 2 hours each at 6 stops in the Morikami Museum and Japanese Gardens. At each stop, the participants made entries into a reflective journal to share their lived experience.

Using the short-form Geriatric Depression Scale (GDS) as a quantitative measure before and after the intervention, the researchers found a statistically significant change in depression scores, with lower scores indicating less depression. For the qualitative aspect of the study, a 4-step thematic analysis of the journal entries included:

- Being forced to spend time away from pressures of the day
- A sense of the beauty of nature
- Using the gardens to provide insight and depth to the experience
- Gratitude for the beauty of nature and the “life I have led”

Level of Evidence: 4

This study is a small descriptive study but includes both quantitative and qualitative methods to study the effect of the intervention for a selected convenience sample.

Commentary: Implications for Practice and Research

Depression is usually treated with psychotherapy and drugs, which often cause adverse drug effects in older adults. When nurses care for older adults with depression, they need to recommend alternative and complementary interventions that may help relieve depressive symptoms and possibly decrease dependence on drug therapy. Using the findings of this study, it is clear that enjoying the beauty of nature and reflecting on life experiences can benefit patients who have been diagnosed with or suspect that they have depression.

! NURSING SAFETY PRIORITY**Action Alert**

Acutely confused patients who are discharged from the hospital are at an increased risk for functional decline, falls, and incontinence at home. Therefore carefully assess older patients in any setting for acute confusion.

A number of tools have been developed for assessing delirium, including the Confusion Assessment Method (CAM), Delirium Index (DI), NEECHAM Confusion Scale, and Mini-Cog (Sendelbach & Guthrie, 2009). Although the CAM is easy to use (Table 3-3), the nurse-developed NEECHAM Confusion Scale is also popular. The CAM consists of nine open-ended questions and a diagnostic algorithm for determining delirium. The Delirium Index is adapted from the CAM and serves as a measure of severity of delirium based on patient observation. The NEECHAM measures the level of confusion in cognitive processing, behavior, and

TABLE 3-3 THE CONFUSION ASSESSMENT METHOD (CAM)

1. Acute onset and fluctuating course (e.g., Is there evidence of an acute change in mental status from the patient's baseline?)
2. Inattention (e.g., Does the patient have difficulty focusing attention or keeping track of what is being said?)
3. Disorganized thinking (e.g., Is the patient's thinking and conversation disorganized or incoherent?)
4. Altered level of consciousness (e.g., Is the patient lethargic, hyperalert, or difficult to arouse?)

The diagnosis of delirium by the CAM is the presence of features 1 and 2 and either 3 or 4.

physiologic control. The lower the patient's score, the more severe his or her delirium is (Lyons et al., 2008).

To help prevent and manage delirium, use a calm voice to frequently reorient the patient. A number of other nursing interventions have been used with some success. For example, playing tapes of soothing music may have a calming effect. Providing a doll or stuffed animal to “fidget” with may prevent the patient from removing important medical tubes or equipment. Some nurses believe that providing dolls and stuffed animals is treating the adult like a child, but this intervention can sometimes be very effective when used for therapeutic purposes. If the patient has a favorite item, such as an afghan blanket or a picture, ask the family or significant others to provide it for the same purpose.

Table 3-4 highlights the major differences between delirium and dementia and lists the major nursing considerations for each. The most difficult challenge is caring for a patient who is experiencing both problems at the same time (Lyons et al., 2008).

Alcohol Use and Abuse

Excessive alcohol consumption increases the risk for falls and other accidents, affects mood and cognitive ability, and leads to complications of chronic diseases like diabetes mellitus, hypertension, and gastroesophageal reflux disease (GERD) (Naegle, 2008). Isolation, depression, and delirium can result from alcohol abuse. The National Institute on Alcohol Abuse and Alcoholism (NIAAA) recommends that people older than 65 years have no more than one alcoholic drink a day or seven drinks in a week (NIAAA, 2011).

The Short Michigan Alcoholism Screening Test—Geriatric Version (SMAST-G) is often used by nurses and other health care professionals in ambulatory care settings to detect alcohol abuse or alcoholism. The 10 yes/no question test is available in English and Spanish and can be either self-administered or administered by a clinician. Examples of questions on the tool are:

- Do you drink to take your mind off your problems?
- When you feel lonely, does having a drink help?

A “yes” answer is worth one point. A total score of 2 or more points indicates that the individual has a problem with alcohol.

Other screening tools for alcohol misuse in older adults include the CAGE questionnaire and the Alcohol-Related Problems Survey (ARPS) and the Short ARPS (shARPS). The acronym CAGE comes from four questions:

- Have you ever tried to cut down on your drinking?
- Have people annoyed you by criticizing your drinking?

TABLE 3-4 DIFFERENCES IN THE CHARACTERISTICS OF DELIRIUM AND DEMENTIA

VARIABLE	DEMENTIA	DELIRIUM
Description	A chronic, progressive cognitive decline	An acute confusional state
Onset	Slow	Fast
Duration	Months to years	Hours to less than 1 month
Cause	Unknown, possibly familial, chemical	Multiple, such as surgery, infection, drugs
Reversibility	None	Usually
Management	Treat signs and symptoms	Remove or treat the cause
Nursing interventions	Reorientation not effective in the late stages; use validation therapy (acknowledge the patient's feelings, and do not argue); provide a safe environment; observe for associated behaviors, such as delusions and hallucinations	Reorient the patient to reality; provide a safe environment

- Have you ever felt bad or guilty about your drinking?
- Have you ever had a drink first thing in the morning to settle your nerves to get rid of a hangover (eye-opener)?

The ARPS and sARPS were created specifically for use with older adults. In a classic study by Fink et al. (2002), these tools were shown to be more sensitive than the SMAST-G and CAGE screening tests in identifying older adults at risk for alcohol abuse. Those who were identified as non-hazardous and harmful drinkers by the ARPS tool were not identified by other tools. These groups were not diagnosed as having alcoholism, but were at risk for this problem.

DECISION-MAKING CHALLENGE

Safety

A 75-year-old man recently lost his life partner after living with him for over 40 years. He visits his physician and reports decreased appetite, extreme fatigue, and insomnia. He also states that he finds it difficult to be in a good mood anymore since his partner died. When giving his medical history, he admits that he is a social drinker and his drinking recently increased.

1. What do you think caused this man's new symptoms and why?
2. As this man's office nurse, what other assessment data do you need to collect? What screening tools might you use?
3. For what is this older adult at high risk and why?
4. With whom might you collaborate to develop his plan of care?
5. What treatment options does this man have?

Elder Neglect and Abuse

Another problem for some older adults is neglect and abuse, both verbal and physical. Some older adults are more vulnerable to these problems than others, especially widows who may have difficulty being assertive. Elder abuse and neglect is a serious problem that affects an estimated 700,000 to 1.2 million older adults each year (Fulmer, 2008). Older persons who are neglected or abused are often physically dependent. The abuser is often a family member who becomes frustrated or distraught over the burden of caring for the older adult. Unfortunately, only 1 case of elder abuse in 10 is reported. Be sure to screen for abuse and neglect of older adults using an appropriate assessment tool.

Prolonged caregiving by a family member is a new and unexpected role for adult children, usually women. This new role may result in role fatigue, conflict, and strain. As a result,

neglect can occur when a caregiver fails to provide for an older adult's basic needs, such as food, clothing, medications, or assistance with ADLs. The caregiver refuses to let other people, like nursing assistants or home care nurses, into the home. Whether intentional or unintentional, neglect accounts for almost half of all cases of actual elder abuse.

Physical abuse is the use of physical force that results in bodily injury, especially in the "bathing suit" zone (abdomen, buttocks, genital area, upper thighs). Examples of physical abuse are hitting, burning, pushing, and molesting the patient. Sedating the older adult is also abusive. **Financial abuse** occurs when the older adult's property or resources are mismanaged or misused; this is more common than physical abuse. **Emotional abuse** is the intentional use of threats, humiliation, intimidation, and isolation toward older adults.

Carefully assess the patient for signs of abuse, such as bruises in clusters or regular patterns; burns, commonly to the buttocks or the soles of the feet; unusual hair loss; or multiple injuries, especially fractures. If the older adult is too weak or has no other resources or support systems, he or she may not admit that abuse is occurring. Neglect may be manifested by pressure ulcers, contractures, dehydration or malnutrition, urine burns, excessive body odor, and listlessness. Depression and dementia are common in community older adults who are abused or neglected.

The Elder Assessment Instrument (EAI) is a 41-item tool that can be used by nurses and other health care professionals to screen for elder abuse and neglect (Fulmer, 2008). The older adult should be referred to the appropriate service when there is:

- Evidence of mistreatment without sufficient clinical explanation
- Complaint by an older adult of being abused or neglected
- A belief by the health care professional that there is a high risk for or probable abuse, neglect, abandonment, or exploitation

All states in the United States and other Western countries have laws requiring health care professionals to report suspected elder abuse. In the community, if physical abuse or neglect is suspected, notify the local Adult Protective Services agency. In a hospital or nursing home, notify the social worker or case manager, who then will report the problem to the appropriate agency.

HEALTH CARE ISSUES FOR OLDER ADULTS IN HOSPITALS AND NURSING HOMES

Older adults who are admitted to hospitals and nursing homes have special needs and potential problems. Many of these problems are similar to those seen among community older adults as discussed in this chapter. Whereas nursing homes have multiple federal and state laws to prevent negative patient outcomes, hospitals are not required to follow these protective laws. However, The Joint Commission and other agencies have recently addressed some of the most common problems seen in older adults. In addition, since 1996, the Hartford Institute for Gerontological Nursing has worked to ensure that all hospitalized patients 65 years of age and older be given quality care.

Nurses may not be aware that the needs of older adults differ from those of younger adults (Fulmer, 2007). Some health care systems have designated Acute Care of the Elderly (ACE) units with geriatric resources nurses and geriatric clinical nurse specialists. The patients are cared for by geriatricians who specialize in the care of older adults.

Other hospitals have developed interdisciplinary programs system-wide to meet the special needs of older patients. The incentive for these new programs is the Nurses Improving Care for Health System Elders (NICHE) project, which continues to generate evidence-based practice guidelines for older adult care.

The purpose of all of these programs and units is to focus on the special health care issues seen in the older population. The **Fulmer SPICES** framework was developed as part of the NICHE project and identifies six serious “marker conditions” that can lead to longer hospital stays, higher medical costs, and even deaths. These conditions are:

- Sleep disorders
- Problems with eating or feeding
- Incontinence
- Confusion
- Evidence of falls
- Skin breakdown

Each of these problems is briefly described here and also is discussed in more detail in other parts of this chapter and the textbook. Other problems, such as depression and constipation, are also common in older hospitalized patients. Rather than being fully comprehensive, the SPICES framework is intended to be an easy tool that has been called “geriatric vital signs” (Fulmer, 2007).

Sleep, Nutrition, and Incontinence

Sleep disorders are common in hospitalized patients, especially older adults. Adequate rest is important for healing, as well as for physical and mental functioning. Pain, chronic disease, environmental noise and lighting, and staff conversations are a few of the many contributing factors to insomnia in the acute and long-term care setting. Assess the patient, and ask how he or she is sleeping. If the patient is not able to answer, observe for restlessness and other behaviors that could indicate lack of adequate rest. Manage the patient’s pain by giving pain medication before bedtime. Attempt to keep patients awake during the day to prevent insomnia. Keep staff conversations as quiet as possible and away from patients’ rooms. Dim the lights to make the patient area as dark as possible. Postpone treatments until waking hours or early

morning if they can be delayed safely. If possible, place a “Do not Disturb” sign on the patient’s door to avoid unnecessary interruptions in sleep (Cole & Richards, 2007).

Problems with eating and feeding prevent the older patient from receiving adequate nutrition. Malnutrition is common among older adults and is associated with poor clinical outcomes, including death. In a study by Volkert et al. (2010), nutrition-related problems were present in half of 205 older patients admitted to a community hospital, but only 8.3% of them received enteral nutrition supplements. The researchers concluded that nutritional screenings and standard protocols should be implemented for older patients in all hospitals. Nurses need to perform nutritional screenings on the first day of patient admission, including a thorough nutritional history, weight, height, and body mass index (BMI) calculation. **Chapter 63** describes nutritional screening in more detail.

Collaborate with the registered dietitian (RD) about the patient’s nutritional status as needed. Consider cultural preferences, and determine what foods the patient likes. Manage symptoms such as pain, nausea, and vomiting. If the patient has difficulty chewing or swallowing, coordinate a plan of care with the speech-language pathologist and dietitian. If there are no dietary restrictions, encourage family members or friends to bring in food that the patient might enjoy. Additional interventions to prevent nutrition-related problems are discussed in **Chapter 63**.

Incontinence varies in type and severity and may be caused by many factors, including acute or chronic disease, ADL ability, and available staff. Assess the patient to identify causes for incontinence. *Incontinence is not a physiologic change of aging, but it is very common in both the hospital and long-term care setting.* Place the patient on a toileting schedule or a bowel or bladder training program, if appropriate. Delegate and supervise this activity to unlicensed assistive personnel. **Chapters 8 and 69** discuss bladder training in detail; **Chapter 8** describes bowel training as well.

Confusion, Falls, and Skin Breakdown

Acute and chronic confusion affect many older patients in both the hospital and nursing home. Whereas chronic confusion states such as dementia are not reversible, acute confusion, or delirium, may be avoidable and is often reversible when the cause is resolved or removed. For example, avoiding multiple drugs and promoting adequate sleep can help prevent acute confusion. Help the patient by reorienting him or her to reality as much as needed. Keep the patient as comfortable as possible; for example, provide interventions to control pain. Delirium is discussed earlier in this chapter. **Chapter 44** describes dementia in detail.

The most common accident among older patients in a hospital or nursing home setting is falling. A **fall** is an unintentional change in body position that results in the patient’s body coming to rest on the floor or ground. Some falls result in serious injuries such as fractures and head trauma. The Joint Commission’s **National Patient Safety Goals (NPSGs)** require that all inpatient health care settings have admission and daily fall risk assessment tools and a fall reduction program for patients who are at high risk.

Assess all older patients for risk for falls. Many assessment tools, such as the Morse Falls Scale, have been developed to help the nurse focus on factors that increase an older person’s risk for falling. **Chart 3-4** lists some of the common risk factors

CHART 3-4 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Assessing Risk Factors and Preventing Falls in Older Adults

Assess for the presence of these risk factors:

- History of falls
- Advanced age (>80 years)
- Multiple illnesses
- Generalized weakness or decreased mobility
- Gait and postural instability
- Disorientation or confusion
- Use of drugs that can cause increased confusion, mobility limitations, or orthostatic hypotension
- Urinary incontinence
- Communication impairments
- Major visual impairment or visual impairment without correction
- Alcohol or other substance abuse
- Location of patient's room away from the nurses' station (in the hospital or nursing home)
- Change of shift or mealtime (in the hospital or nursing home)

Implement these nursing interventions for all patients, regardless of risk:

- Monitor the patient's activities and behavior as often as possible, preferably every 30 to 60 minutes.
- Teach the patient and family about the Fall Prevention program to become safety partners.
- Remind the patient to call for help before getting out of bed or a chair.
- Help the patient to get out of bed or a chair if needed; lock all equipment, such as beds and wheelchairs, before transferring patients.
- Teach patients to use the grab bars when walking in the hall without assistive devices or when using the bathroom.

- Provide or remind the patient to use a walker or cane for ambulating if needed; educate him or her on how to use these devices.
- Remind the patient to wear eyeglasses or a hearing aid if needed.
- Help the incontinent patient to toilet every 1 to 2 hours.
- Clean up spills immediately.
- Arrange the furniture in the patient's room or hallway to eliminate clutter or obstacles that could contribute to a fall.
- Provide adequate lighting at all times, especially at night.
- Observe for side effects and toxic effects of drug therapy.
- Orient the patient to the environment.
- Keep the call light and patient care articles within reach; ensure that the patient can use the call light.
- Place the bed in the lowest position with the brakes locked.
- Place objects that the patient needs within reach.
- Ensure that adequate handrails are present in the patient's room, bathroom, and hall.
- Have the physical therapist assess the patient for mobility and safety.

For patients at a high risk for falls:

- Implement all assessments and interventions listed above.
- Relocate the patient for best visibility and supervision.
- Encourage family members or significant other to stay with the patient.
- Collaborate with other members of the health care team, especially the rehabilitative services.
- Use technologic devices to alert staff to patients getting out of bed, such as mattress sensor pads.
- Use low beds or futon-type beds to prevent injury if the patient falls out of bed.

that should be assessed and evidence-based, collaborative interventions for preventing falls in high-risk patients. *A recent history of falling is the single most important predictor for falls.*

Older patients often have **nocturia** (urination at night) and get out of bed to go to the bathroom. They may forget to ask for assistance and may subsequently fall as a result of disorientation in the darkness in an unfamiliar environment. In some cases, they may crawl over the siderail, which can make the fall more serious. Because of this, full or split siderails are used far less often in both hospitals and nursing homes. In both settings, siderails are classified as restraints unless the use of rails helps patients increase mobility.

A **restraint** is any device or drug that prevents the patient from moving freely and must be prescribed by a health care provider. In 1990, the federal government enforced a law that gives nursing home residents the right to be restraint free. Removing physical restraints from nursing home residents has reduced serious injuries, although falls and minor injuries have increased in some cases. Mattresses placed on floors next to patient beds or "low beds" have helped reduce injury. The Joint Commission's NPSGs require hospitals to reduce the risk for patient harm resulting from falls.

Hospitals have also reduced the use of physical restraints. The Joint Commission has specific standards that limit the use of physical restraints in hospitals and nursing homes. Chemical restraints (psychoactive drugs) such as haloperidol (Haldol) have sometimes been used in place of physical restraints.

Experts agree that older adults should not be placed in a physical restraint or sedated just because they are old. Use alternatives before applying any type of restraint (Chart 3-5). However, if all other interventions (e.g., reminding patients to call for assistance when needed; asking a family member to stay with patients) are not effective in fall prevention, a physical restraint may be required for a limited period. Applying a restraint is a serious intervention and should be analyzed for its risk versus its benefit. Check the patient in a restraint every 30 to 60 minutes, and release the restraint at least every 2 hours for turning, repositioning, and toileting. Physical restraints such as vests have caused serious injury and even death. *If restraint is needed, use the least restrictive device first. Be sure to follow your facility's policy and procedure for using restraints.*

Chemical restraints are often overused in hospital settings. Examples include:

- Antipsychotic drugs
- Antianxiety drugs
- Antidepressant drugs
- Sedative-hypnotic drugs

The most potent group of psychoactive drugs is the antipsychotics. These drugs are appropriate only for the control of certain behavioral problems, such as delusions, acute psychosis, and schizophrenia. Typical antipsychotic drugs include haloperidol (Haldol, Peridol ) and thiothixene (Navane). These drugs should not be used to treat anxiety or induce sedation.

CHART 3-5 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Using Restraint Alternatives

- If the patient is acutely confused, reorient him or her to reality as often as possible.
- If the patient has dementia, use validation to reaffirm his or her feelings and concerns.
- Check the patient often, at least every hour.
- If the patient pulls tubes and lines, cover them with roller gauze or another protective device; be sure that IV insertion sites are visible for assessment.
- Keep the patient busy, with an activity, pillow or apron, puzzle, or art project.
- Provide soft, calming music.
- Place the patient in an area where he or she can be supervised. (If the patient is agitated, do not place him or her in a noisy area.)
- Turn off the television if the patient is agitated.
- Ask a family member or friend to stay with the patient at night.
- Help the patient to toilet every 2 to 3 hours, including during the night.
- Be sure that the patient's needs for food, fluids, and comfort are met.
- If agency policy allows, provide the patient with a pet visit.
- Provide familiar objects or cherished items that the patient can touch.
- Document the use of all alternative interventions.
- If a restraint is applied, use the least restrictive device (e.g., mitts rather than wrist restraints, a roller belt rather than a vest).

! NURSING SAFETY PRIORITY**Drug Alert**

Closely monitor older adults receiving antipsychotics for adverse drug events (ADEs). Assess patients for:

- Anticholinergic effects, the most common problem, causing constipation, dry mouth, and urinary retention
- Orthostatic hypotension, which increases the patient's risk for falls and fractures
- Parkinsonism, including tremors, bradycardia, and a shuffling gait
- Restlessness and the inability to stay still in any one position
- Hyperglycemia and diabetes mellitus, which occur more with drugs like risperidone (Risperdal) and quetiapine (Seroquel) (Abdallah et al., 2008)

If any of these ADEs occur, notify the health care provider immediately.

Skin breakdown, especially pressure ulcers, is a major problem among older adults in hospitals and nursing homes. In some cases, these wounds cause death from infection. Therefore prevention is the best approach. The Joint Commission's NPSGs require that all health care agencies have a program to prevent agency-associated pressure ulcers. The program should include these evidence-based interventions:

- Nutritional support
- Avoidance of skin injury from friction or shearing forces

- Repositioning and support surfaces
- A plan to increase mobility and activity level, when appropriate
- Skin cleansing and use of moisture barriers

Assess older adults for their risk for pressure ulcers, using an assessment tool such as the Braden Scale for Predicting Pressure Sore Risk (see [Chapter 27](#)). Implement evidence-based interventions to prevent agency-acquired pressure ulcers. Coordinate these interventions with members of the health care team, including the dietitian and wound care specialist.

! NURSING SAFETY PRIORITY**Action Alert**

Supervise unlicensed assistive personnel (UAP) for frequent turning and repositioning for the patient who is immobile. Assess the skin every 8 hours for reddened areas that do not blanch. Remind UAP to keep the skin clean and dry. Use pressure-relieving mattresses, and avoid briefs or absorbent pads that can cause skin irritation and excess moisture. [Chapter 27](#) describes additional interventions for prevention and management of pressure ulcers in detail.

Skin tears are also common in older adults, especially the old-old group and those who are on chronic steroid therapy. Teach UAP to use extreme caution when handling these patients. Use a gentle touch, and report any open areas. Avoid bruising because older adults have increased capillary fragility.

GET READY FOR THE NCLEX® EXAMINATION!**KEY POINTS**

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Coordinate care by collaborating with members of the health care team when providing care to older adults in the community or inpatient setting.
- Assess all older adults for risk for falls and driving ability (see [Charts 3-3 and 3-4](#)).

- Assess for signs of elder neglect and abuse; if suspected, it should be reported.
- Physical and chemical restraints should not be used for older adults until all other alternatives have been tried.
- Follow The Joint Commission's National Patient Safety Goals and federal/state standards when using patient restraints.

GET READY FOR THE NCLEX® EXAMINATION! —cont'd**Health Promotion and Maintenance**

- Relocation stress syndrome is the reaction of an older adult when transferred to a different environment; ways to minimize this problem are listed in [Chart 3-2](#).
- Decreased nutrition and mobility are two health problems experienced by older adults.
- Teach older adults about the benefits of regular physical exercise.
- Provide information regarding community resources for older adults to help them meet their basic needs.
- Teach health promotion practices as listed in [Chart 3-1](#).

Psychosocial Integrity

- Depression is the most common yet most underdiagnosed and undertreated mental health/behavioral health disorder among older adults.
- Delirium is acute confusion; dementia is chronic confusion (see [Tables 3-3 and 3-4](#)). Confusion is not part of the normal aging process.
- Screen older adults for alcohol abuse or alcoholism, and refer those with identified problems to appropriate resources.
- Elder neglect and abuse are serious problems; family caregivers are usually the abusers.
- Many older adults return to work to help pay for health care and other expenses and to provide socialization.

Physiological Integrity

- The four subgroups of the older adult population are the young old, middle old, old old, and elite old.
- The biggest concern regarding accidents among older adults in both the community and inpatient setting is falls.
- Physiologic changes of aging predispose older adults to toxic effects of medication; drugs are absorbed, metabolized, and distributed more slowly than in younger people. They are also excreted more slowly by the kidneys.
- Medication use in older adults is often a problem when they commit errors when self-medicating, avoid needed medications, or have problems understanding their medication regimen.
- Follow The Joint Commission's National Patient Safety Goals and best practice guidelines to prevent agency-acquired pressure ulcers.
- Promote sleep and rest for older adults to decrease the incidence of delirium and to prevent falls.
- Use alternatives for physical or chemical restraints to provide patient safety, as listed in [Chart 3-5](#).
- Use the SPICES assessment tool for identifying serious health problems that can be prevented or managed early.

Cultural Aspects of Health and Illness

LEARNING OUTCOMES

Health Promotion and Maintenance

1. Explain the purpose of *Healthy People 2020* as related to culture.
2. Incorporate cultural practices and beliefs into the patient's plan of care.

Psychosocial Integrity

3. Define culture, cultural diversity, cultural competence, and cultural sensitivity.
4. Discuss specific cultural practices, such as family roles and nutrition, which should be part of a cultural assessment.

5. Describe the best approach for caring for patients who are homeless.
6. Identify two major health issues related to the lesbian, gay, bisexual, and transgender (LGBT) population.
7. Identify two influences of culture on drug therapy.
8. Collaborate with the professional chaplain to manage a patient's spiritual distress.
9. Describe two examples of generic and folk medicine that are used in the United States today.
10. Explain ways that nurses can communicate sensitively with patients from various cultural groups.

In the 1950s, Madeline Leininger, a nurse anthropologist and theorist, provided a large body of knowledge called transcultural nursing. She defined **transcultural nursing** as an area of study and practice that focuses on the care, health, and illness patterns of people with similarities and differences in their cultural beliefs, values, and practices. Since that time, other researchers have continued her work as the United States has become more culturally diverse.

It is still the case that the majority of people in the United States are white and of European descent (Euro-American;

also called *Caucasian*). However, the population is increasing by more than 2.5 million people *each year*, and 1 million of them are newcomers (also called *immigrants*) from other countries. In 2008, the number of minority populations in the United States accounted for 31% of the total population; Hispanics/Latinos are the largest minority group at over 15%; the black population represents about 12%. Asian Americans are currently the fastest growing group at 5% of the U.S. population.

In addition to racial and ethnic diversity, people differ in gender, age (generation), education, occupation, geographic location, and religion. Each of these differences represents varying cultures. As a nurse, you will care for many diverse patients and work with diverse staff. Therefore you will need to learn about cultural diversity and become culturally competent.

*Special thanks to Stephanie M. Ignatavicius, B.A., for her contributions to this chapter in these areas: LGBT, homeless, and little people issues.

FIG. 4-1 Healthy self-esteem in young adulthood is tied to appreciation of one's cultural heritage. These Korean Americans demonstrate pride in their cultural heritage through participation in a cultural celebration.

CULTURE AND CULTURAL COMPETENCE

When considering cultural aspects of health, nurses and other health care staff need to understand the differences in commonly used terms: culture, cultural diversity, cultural competency, and cultural sensitivity. Culture is not restricted to race or ethnicity. Instead, **culture** is a broad term that refers to integrated patterns of behavior acquired over time, including beliefs, values, customs, norms, habits, language, thoughts, and ways of life. It is learned and transmitted primarily within the family unit, generation, and/or other social organizations and is shared by most of the members of the group. A person's culture provides his or her worldview, which helps guide decision making and enhances self-worth (Fig. 4-1). Be sure to respect the clinical decisions made by all patients and their families, even if they differ from what you think the decisions should be.

Cultural diversity refers to differences among people, which may or may not be visible. For example, a person's *race* describes his or her visible physical characteristics, such as skin tone, head shape, and hair texture. *Ethnicity* describes common social customs, values, and beliefs of a group. *A person's race does not determine his or her ethnicity.* For instance, a woman may be white and of Russian descent. Therefore her customs and beliefs about health care or family roles may be different from those of a white woman from Italian ancestry. Another example is the use of the U.S. census category "African American," which implies that all black people come from an African background. There are a number of problems with that assumption. First, all African countries do not have the same customs and values. Second, although many black people are of African heritage, some are from Haiti, Jamaica, and other countries. Therefore to refer to all black people as African American is not culturally correct or sensitive.

Cultural competence is a process that involves respecting all differences and not letting one's own biases influence others. It requires having the knowledge, skills, and

TABLE 4-1 CAMPINHA-BACOTE'S ASKED MODEL OF CULTURAL COMPETENCE

Awareness: Are you aware of your personal biases and prejudices toward cultures different from yours?
Skill: Do you have the skill to conduct a cultural assessment and perform a culturally based physical assessment?
Knowledge: Do you have knowledge of the patient's worldview (the way that a person looks at the universe to form values in his or her life and the world)?
Encounters: How many face-to-face encounters have you had with patients from diverse cultural backgrounds?
Desire: What is your desire to want to be culturally competent?

Data from Dr. Josie Campinha-Bacote, expert in cultural nursing.

understanding about diverse groups. In health care, cultural competence refers to the *ability of health care providers and organizations to understand and respond effectively to the cultural and linguistic needs that patients bring to the health care setting.* The Joint Commission standards and National Patient Safety Goals require that cultural differences be respected and incorporated into the plan of care for patient safety and quality care.

Becoming culturally competent first requires you to examine your feelings and experiences regarding diversity, starting with an understanding of your own heritage. Then you will need to learn more about specific cultural differences so you can develop an appreciation for the values and beliefs of both patients and staff co-workers. Campinha-Bacote's (2003) **ASKED** Model of Cultural Competence provides a beginning, basic self-assessment tool. Ask yourself the questions listed in Table 4-1.

Cultural sensitivity occurs when a person is aware of, respects, and appreciates cultural differences and thus avoids biased, negative, impolite, and offensive language and actions when interacting with people of diverse cultures. Sensitivity also means avoiding stereotyping. **Stereotyping** occurs when you assume that all people in a particular culture have the group's values and beliefs or practice the group's customs. Everyone in a particular group is a unique person.

Some groups continually strive to preserve their heritage. The most common example is the American Indian (also called Native American) population, which consists of many subgroups, also called *councils* or *nations*, across the United States. This multi-cultural group teaches the importance of maintaining traditions from generation to generation. However, specific beliefs and rituals vary among its subgroups. For instance, the Lakota council is made up of several tribes that have specific customs. These customs differ from those of other American Indians like the Cherokee or Navajo nations. However, some generalizations apply to all American Indians, such as their value for respect, spirituality, and nature.

According to U.S. government treaties in the 1800s, the Lakotas and other like subgroups are American Indians, not Native Americans. For that reason, they prefer to call themselves *American Indian* because that is their legal designated name (Ogala Lakota College, Pine Ridge, SD, personal communication, August 6, 2003). This textbook uses *American Indian* rather than *Native American* to refer to this large cultural group. Keep in mind that other nations or pueblos may prefer the term *Native Americans*. Remember to always ask the

patient what term he or she prefers and use that term during conversation.

HEALTH AND HEALTH CARE DISPARITIES

Health disparities are the differences in the incidence of health care problems among minority racial and ethnic groups when compared with the white majority. To date, no research has definitely supported either a genetic or environmental cause for these disparities, but both may contribute to the problem. Disparities in health care quality may also help explain the differences in health status among minority groups. Possible factors that may contribute to this problem include socioeconomic status, individual discrimination, access to care, and language barriers.

The *Healthy People 2020* health promotion initiative reflects assessments of major risks to health and wellness, changing public health priorities, and emerging issues related to our nation's health preparedness and prevention, including reducing disparities in health and health care among populations living in the United States. Whereas many objectives of the initiative are the same as those of *Healthy People 2010*, many others were modified and some objectives were added. Several new areas of public health concern were added to the list or greatly expanded, such as access to health care, genomics, and global health. Where appropriate, this book includes tables that outline specific *Healthy People 2020* objectives with abbreviated action plans related to selected health problems or health care issues.

PURNELL'S DOMAINS OF CULTURE

No one is expected to know the specific traits of every type of culture, including racial and ethnic groups. But you will need to continue learning as you interact with more and more diverse groups to develop cultural competence. Purnell & Paulanka (2008) have suggested 12 essential areas, or domains, to assess and understand any culture (Table 4-2). The most relevant of these cultural practices for nursing care are briefly reviewed here.

Culture Overview and Communication

The first domain includes *overview and localities*. This area refers to a person's residence (where he or she lives), heritage, education, and occupation.

Overview and Localities

The ancestors of a large portion of the U.S. population left their native countries many decades or centuries ago. One of

the biggest movements of newcomers was in the early 1940s. Many of these people were European, fleeing persecution or war-torn countries. More recent immigrants come to the United States for better opportunities for education, jobs, religious freedom, and democracy (Purnell & Paulanka, 2008).

Although ethnic minorities can be found anywhere throughout the United States, some have chosen to live in specific geographic areas with members of their culture for support and practice of traditional customs. For example, Asian Americans are concentrated in New York City and California. Hispanics, especially Mexicans and Latinos, tend to reside in the Southwestern United States, Texas, Florida, and California (Purnell & Paulanka, 2008). New York City also has a high percentage of people of Hispanic descent.

Other types of cultural groups are also attracted to specific geographic locations. For instance, older adults tend to retire to warmer climates like Florida and Arizona. Many younger people are attracted to large urban areas for access to multiple social activities and job opportunities. When you are caring for patients, assess where they live and whether they have a support system within their culture.

Homelessness

A special group of people, the *homeless*, is increasing because of the recent recession and high unemployment. According to the National Coalition for the Homeless, each night in the United States, an estimated 700,000 to 800,000 people are homeless (National Coalition for the Homeless, 2009). The homeless are a mix of people who vary in age, ethnicity, education, and occupation. In the past 10 years, this group has become increasingly diverse. Most homeless people are single adults with little or no family support.

Homelessness can be either absolute or relative. Absolute homelessness is defined as having no physical home; those who are relatively homeless have some sort of shelter, although it may not be safe or sanitary (Badiaga et al., 2008). The severity of health care needs of this population is increasing while available resources are shrinking (Drury, 2008). Most patients use the emergency department for primary care and seek health care only because of complications of chronic disease. In many cases, these complications could be prevented with consistent treatment and follow-up. Major reasons that explain why the homeless avoid the health care community include (Jones et al., 2009):

- Mistrust of health care providers
- Fear of discrimination
- Language barriers
- Inability to understand medical information
- Inability to adhere to treatment

The homeless are particularly prone to *cardiovascular disease* (CVD) because of poor nutrition, stress, and lack of preventive and follow-up care. The stress of being homeless, coupled with lack of ongoing health care, leads to hypertension, diabetes mellitus, and high cholesterol (Jones et al., 2009). To add to these risks, the typical diet of a homeless person includes high intake of saturated fats, sodium, and cholesterol. Stress-coping behaviors such as smoking, excessive alcohol, and illicit drug use also increase the risk for CVD.

Poor nutrition, alcohol, and stress also increase the risk for *infection* among homeless people. Common infections in this population include tuberculosis, human immune deficiency

TABLE 4-2 PURNELL'S DOMAINS FOR ASSESSING CULTURAL GROUPS OR PERSONS

• Nutrition • Communication • Family roles and organization • Workforce issues • Biocultural ecology • High-risk behaviors	• Overview (e.g., heritage) • Pregnancy and childbirth practices • Death rituals • Spirituality • Health care practices • Health care practitioners
---	--

Data from Purnell, L. (2000). A description of the Purnell model for cultural competence. *Journal of Transcultural Nursing*, 11(1), 40-46.

virus (HIV), hepatitis B and hepatitis C, and skin disorders such as scabies and pediculosis (body lice). These infections occur as a result of:

- Staying in overcrowded shelters
- Using IV drugs
- Having limited access to bathing and clean clothing
- Sharing bedding and clothing with others
- Having sex with multiple partners, especially without condoms

Mental health disorders are particularly common among the homeless population. According to the Interagency Council on Homelessness, 36% are chronic substance abusers and over 26% have other mental health problems; 17% are veterans of war (Interagency Council on Homelessness, 2009). The homeless are also exposed to unsafe environments that can cause illness, trauma, or death, such as violence and extremes of heat and cold.

! NURSING SAFETY PRIORITY

Action Alert

The primary approach to caring for a homeless patient is to establish trust. Many of these patients have experienced discrimination and therefore do not trust nurses or other health care professionals. When talking with a homeless patient, avoid discriminatory language and do not make assumptions. Take time to communicate, empathize, and show concern to build trust and assess the patient's needs (Drury, 2008; Jones et al., 2009).

Second, while caring for the patient, remember that he or she does not have the same comforts as other patients, such as adequate bathing, cooking, and rest areas. These obstacles need to be considered when developing an ongoing plan of care. Ask the patient what resources he or she has available.

To compensate for limited time with homeless patients, develop a simple treatment plan. Fill prescriptions, provide supplies, and give necessary immunizations and screening tests so that fewer visits might be needed (Drury, 2008).

Communication

Another area to assess in Purnell's first domain of culture is the ability of your patient to *communicate*. Language continues to be the largest barrier for people who do not speak English or cannot communicate in English effectively. If your patient is not fluent in English, determine his or her primary language. The Joint Commission National Patient Safety Goals require that professional *interpreters* (also called *trained medical interpreters* or *medical language interpreters*) be available in health care facilities to prevent errors in communication that could lead to patient harm. In addition, telephone interviews with patients who cannot communicate in English should involve the use of telephonic interpretation services, such as Language Line Services (www.language-line.com) or Language Services Associates (www.lsaweb.com). **Chart 4-1** lists guidelines to help you communicate with non-English-speaking patients. Remember that many groups (e.g., Japanese Americans, Appalachians, and Mexican Americans) are not as open with expressing their feelings to strangers as most Euro-Americans.

Communication also includes nonverbal forms, such as body language, eye contact, facial expression, and touch. *Be sure to find out which forms are acceptable for your patient.* For instance, eye contact can be interpreted differently depending

CHART 4-1 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Guidelines for Communicating with Non-English-Speaking Patients

- Use dialect-specific interpreters who are the same gender and about the same age as the patient if possible.
- Use interpreters who are familiar with health and health care.
- Avoid the use of relatives to prevent bias and misinterpretation.
- Speak slowly, and allow the patient time to translate and process what is being discussed.
- Use common words in the patient's language if known; become familiar with Spanish terms that are frequently used in health care.
- Maintain eye contact with the patient and family while communicating, unless it is not culturally acceptable.
- Remember that most patients can understand English better than they can speak it.
- Be careful with nonverbal facial expressions and body language.

on the patient's cultural background. Some American Indians find it offensive to make direct eye contact. Many Middle-Eastern cultures are not likely to accept touch by strangers.

NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

A homeless client enters the emergency department smelling strongly of alcohol and having an offensive body odor. He is drowsy and disoriented and has a staggering gait. What is the nurse's first priority in caring for this client?

- Establish trust to enhance communication.
- Notify the social worker or case manager on call.
- Keep the client safe to prevent a fall or other injury.
- Ask a nursing assistant to bathe the client.

Family and Workplace Issues

Ask about *family roles, organization, and lifestyle*, as well as *workforce issues*. Information about family and gender roles will influence your plan of care. For example, an Arab Muslim woman cannot be exposed and only a female is allowed to care for her. If you are preparing the patient for a procedure, keep her entire body including her head covered and provide additional draping. Make sure that all staff caring for her are female.

Assess who makes the decisions in the family; do not assume that the patient will want to make them. Autonomy and independence are traditional Euro-American values but may not be valued by some patients. The family as a unit may make decisions—not the individual patient. In cultures in which men dominate, the husband makes all decisions for the woman. If the woman works outside the home, she may have difficulty being assertive or making workplace decisions. This is especially true among Nigerian, Chinese, and Iranian women (Purnell & Paulanka, 2008).

In some cultures, entire families insist on staying with patients while they are hospitalized to show their love and support. On the other hand, some patients may not want family members present. Strive to meet the needs of your patients and negotiate with both families and administration. For example, request extra cots or recliners for family sleeping arrangements, if possible.

Another aspect of family roles and organization is how members view and treat their older adult relatives. Some groups, such as Asian subcultures, highly value and respect older adults. Euro-Americans tend to value children and their immediate nuclear families more than their extended families, including grandparents, cousins, and uncles.

The makeup of a family in the United States varies greatly. For example, some families have single parents; some have same-sex parents, and others have grandparents who rear their grandchildren. Domestic partnerships without the formality of marriage with the opposite or same gender are also very common and acceptable in most societies. However, the health status and the quality of health care may differ depending on a person's sexual identity. Do not assume that every patient is heterosexual or clearly gendered. *Include questions about sexual identity and sexual activity as part of your patient's health assessment.*

The health care system, like other facets of society, often overlooks sexualities and genders that are alternative to the standard of heterosexuality and clearly delineated maleness or femaleness. As a health care professional, it is essential to not be restricted by rigid standards of identity. A good way of rethinking concepts of sexuality and gender is to think of each as existing along a spectrum as opposed to the confinement of heterosexual/homosexual and male/female. This textbook uses **LGBT** to refer to the lesbian, gay, bisexual, and transgender population to best characterize the spectrum of identities. This terminology is widely accepted by the LGBT community and is commonly seen in the literature. This term is also known as **LGBTQI** to include questioning/queer and intersex individuals. Questioning or queer individuals prefer not having strict labels on their sexualities or genders; intersex individuals have ambiguous genitals or other reproductive anatomy.

Members within this population vary by race, ethnicity, and age. The exact size of the group is not known, but it is estimated to be between 2% and 5% of the adult U.S. population (Mayer et al., 2008).

Lesbian, Gay, Bisexual, and Transgender Health

LGBT health has not been widely studied because the group is very diverse. Selecting an accurate sample is difficult and therefore may not represent the entire group. As a result, any research findings may be less reliable than desired and more difficult to generalize for the entire culture.

In 1999, the Institute of Medicine (IOM) drafted a classic document to summarize its findings of *lesbian health* and recommendations for improvement. In 2001, the United States Department of Health and Human Services (USDHHS) published a companion document for the *Healthy People 2010* program on LGBT health. However, the research findings may have limitations because of inaccuracies in sample identity.

Using the best evidence available, the USDHHS report outlined major health disparities between lesbian and non-lesbian women. Women who identify as lesbians have a higher incidence of substance abuse and obesity than non-lesbian women. In addition, lesbians are twice as likely to smoke heavily when compared with their non-lesbian counterparts. These factors make lesbians more prone to lung cancer, cardiovascular disease (CVD), and other health issues associated with smoking and obesity (USDHHS, 2001). Greater rates of substance abuse, obesity, and smoking may be the result of

stress experienced by minority groups and the internalization of the homophobia (fear of LGBT people) they encounter on a regular basis (Hamilton & Mahalik, 2009). This stress may also be a contributing factor to the high incidence of depression and suicide among lesbians.

Lesbians are also at greater risk for women-specific cancers, including breast, ovarian, and cervical cancers because of several factors (USDHHS, 2001):

- Substance abuse, obesity, and smoking are cancer risks.
- Nulliparity (not giving birth to a child) or low parity is also a risk factor for gynecologic cancer.
- Lesbians are less likely to have routine mammograms, pap smears, and sexually transmitted disease (STD) testing because of the false assumption that lack of heterosexual sex eliminates their risk for these problems.

Bisexual women engage in more substance abuse than heterosexual women. They also report more frequent episodes of back problems, digestive disorders, and chronic fatigue. The causes of these differences are not well-researched (Weisz, 2009).

Gay men or men having sex with men have a higher incidence of anal and colon cancer than other men. Emerging research suggests that routine anal Pap testing for HIV-infected men helps detect anal cancer early so that it can be treated successfully (Mayer et al., 2008).

Recent studies have linked stress from homophobia and pressure to conform to the masculine ideal to health issues in gay men, including substance abuse, risky sexual behaviors, eating disorders, and high rates of depression and suicide (Hamilton & Mahalik, 2009). Acquired immune deficiency syndrome (AIDS)-related complications such as Kaposi's sarcoma are also more likely to occur in gay men when compared with other men (USDHHS, 2001).

Transgender people often undergo hormone therapy to facilitate their transitions to the desired gender. Exogenous hormones can lead to cardiovascular risks, especially for those who also smoke, are older, are obese, and/or have a history of hypertension or other CVD. Biologic males taking estrogens and progestins to transition to being female may also develop thrombosis, liver disease, and diabetes mellitus. Biologic females taking testosterone may have high serum lipid levels, infertility, and benign or malignant hepatic tumors. Cross-sex hormone therapy can also increase serum lipids in those who are HIV-infected (Mayer et al., 2008).

Quality of LGBT Health Care

LGBT people experience prejudice and hostility frequently in their lives; they should not need to fear this type of treatment from health care professionals. As a result of this fear, many are hesitant to seek medical treatment or have routine check-ups and screening tests. Health care professionals should provide culturally safe care and respect patient diversity. Respect the patient's right to have his or her partner present when interacting with the health care community.

Part of culturally safe care requires that nurses and other providers know their patient's sexual and gender identities. When learning the patient's name, establish his or her preferred gender identity and pronoun (he or she); do not assume this identity based on appearance. Document the patient's identity on the assessment form. Assessment forms traditionally ask questions such as "Are you

TABLE 4-3 RECOMMENDED PATIENT INTERVIEW QUESTIONS ABOUT SEXUAL IDENTITY AND HEALTH CARE

- Do you have sex with men, women, with both, or neither?
- Does anyone live with you in your household?
- Are you in a relationship with someone who does not live with you?
- If you have a sexual partner, have you or your partner been evaluated about the possibility of transmitting infections to each other?
- If you have more than one sexual partner, how are you protecting both of you from infections, such as hepatitis B or hepatitis C or HIV?
- Have you disclosed your sexual identity and sexual activity to your health care provider?
- If you have not, may I have your permission to provide that information to members of the health care team who are involved in your care?
- Who do you consider as your closest family members?

HIV, Human immune deficiency virus.

married, divorced, widowed, or single?” Using this question, there is no option for LGBT patients to answer. This type of barrier interferes with communication between the patient and the nurse. Better questions to ask about sexual identity during a patient interview are recommended in Table 4-3.

Once trust and communication have been established, teach patients about the need for screening tests and health promotion activities to decrease risks. Refer patients who are substance abusers or depressed to a mental health specialist or substance abuse intervention programs as needed.

Biologic Ecology

Biologic ecology includes biologic variations, health disparities, and drug metabolism differences. Race/ethnic, gender, and health disparities have been discussed. A common biologic variation relates to adult body size and type, such as dwarfism.

Dwarfism

People with dwarfism are defined as having a height below 4 feet 10 inches and are properly referred to as *little people (LP)*, *dwarves*, or *short-statured*. Dwarfism presents in numerous forms. All forms of dwarfism are considered as either proportionate or disproportionate. Proportionate LP are smaller versions of average-height people, whereas disproportionate LP have limbs and features that are not in proportion with the relative size of their other parts. Dwarfism results most often from genetic mutations and hormone imbalance.

Little people experience many health problems as they age. Common problems include arthritis, hydrocephaly, ear infections, and obesity. LP often have curvature and/or compression of the spine and may have knock-knees or bow-legs. These conditions can be very painful and require drug therapy. Patients with achondroplasia have a higher risk for spinal stenosis. Those with hydrocephalus may have shunts.

LP also have numerous ear infections that may require a myringotomy to insert ear tubes. Females with dwarfism are more likely to experience menstrual complications, reduced fertility, fibroids, and early menopause than average-height women.

Many LP require surgeries to treat skeletal abnormalities, such as spinal fusion, laminectomy, total joint replacement, and osteotomy (to correct bowed or knock-knee legs). They may also have leg-lengthening surgeries in which the leg bones are broken and screws are inserted and regularly rotated in miniscule increments to lengthen the bones as they heal.

When taking care of patients after surgery, be aware that they may be at high risk for falls because of their size. LP often require adaptive resources such as footstools and reaching tools to perform ADLs independently. Be sure to know their health history because previous health problems and surgeries can affect the management of current problems.

Like all patients, little people often benefit from support groups in their community. The largest nonprofit organization for this population is the Little People of America (LPA) (www.lpaonline.org). The primary purpose of this organization is to provide parent and peer support for people of short stature. Refer patients to the state chapter of the LPA if they are interested in resources and peer support.

Ethnopharmacology

A new field related to culture is ethnopharmacology. **Ethnopharmacology** is the study of the effect of ethnicity on how drugs work in the body, including drug absorption, distribution, metabolism, and excretion. For example, some angiotensin-converting enzyme (ACE) inhibitors for hypertension typically work better for Euro-American patients than for African Americans and other blacks. On the other hand, the thiazide diuretics are more effective for lowering blood pressure in African Americans and other blacks when compared with Euro-Americans. The exact causes for these differences are being studied. Although nurse generalists do not prescribe drug therapy, they need to understand why selected drugs are given to certain groups.

The lifestyle and values of patients can also affect drug response. For instance, excess tobacco and alcohol use can increase or decrease the rate at which a drug is metabolized and excreted, depending on the specific drug. Another concern about drug therapy is whether the patient adheres to the drug regimen. For example, older adults may be less likely than younger adults to follow the prescribed therapy because of drug costs. The reasons for the differences among cultural groups are unknown but may include language or transportation barriers. Consider these cultural factors when teaching patients about their drug therapy.

Nutrition

Nutritional assessment is part of the comprehensive health assessment (see Chapter 63). Determine what food means to your patient and which foods are preferred. For example, Korean and Chinese foods tend to be high in salt; other Asian cultures prepare very spicy food that can contribute to GI cancers. Also assess the patient's eating patterns, which may be different from your own. Some patients are vegetarians; others are vegan (no food or food products made with dairy, eggs, or meat). Respect the patient's preferences and beliefs about food and what it means to them.

Rituals and customs surrounding food are also important to assess. American Indian subgroups often celebrate Feast Days. Muslims may observe Ramadan by fasting during the day; Catholics may give up a certain food during Lent. The British have tea in the afternoon, and many people in

the United States have coffee during their morning breaks. Hot dogs and sports events seem to go together, and turkey is traditionally served at Thanksgiving. Assess how your patient connects food with customs or rituals, especially if the patient is being cared for during one of these special times.

Some ethnic groups have food intolerances. For example, many Vietnamese Americans, African Americans, and other blacks are lactose intolerant. Some Greek Americans have glucose-6-phosphate dehydrogenase deficiency, an enzyme problem (Purnell & Paulanka, 2008). Coordinate the diet with the registered dietitian to ensure that patients receive foods that they can tolerate and are culturally appropriate. For new immigrants who may not know where to obtain ethnic foods, provide a list of specialty stores in the community.

Spirituality

Spirituality is a broad concept that involves the behaviors that give purpose to life and provide individual strength; it may or may not include religious practices. Religion is a more narrow term and refers to a formal belief system that is expressed in public.

Only some of your patients will state their religion, but everyone is spiritual, including people who do not believe in God or other Supreme Being. Therefore many of your patients will have spiritual needs or experience spiritual distress. Patients often rate emotional and spiritual needs as an important aspect of their hospital care. Spiritual practices such as prayer often influence patient healing. Helping patients meet their spiritual needs improves satisfaction and helps them cope with their health problems or crisis. *Respect your patient's beliefs about religion and spirituality, even if they differ from your own.*

The Joint Commission requires all health care facilities and agencies to address the spiritual needs of their patients. Yet nurses may not know how to help them or may not feel they have time for this aspect of care. Today professional chaplains are specifically trained and certified to help patients meet their spiritual needs in hospitals and other health care agencies.

Since 2000, The Joint Commission has required hospitals to have a qualified chaplain as part of the health care team. Chaplains may come from any religious affiliation, but all must know about health problems, health care, and interpersonal skills. Although they may perform religious ceremonies or rituals, their role is much broader. Chaplains have the time and expertise to manage spiritual distress. They are uniquely qualified to help patients cope with their responses to health crises, which are typically guilt and anger. They can also assist families to allay fear and anxiety and help them cope with their loved one's illness or end of life. Collaborate with your facility's chaplain if patients or families have any of these needs.

In addition to providing direct services to patients and their families, chaplains can be a liaison between patients and families and clinical staff. They can also support staff when difficult situations occur, such as a serious illness or death of a staff member. Do not hesitate to ask a chaplain to help you or your health care team.

Health Care Practices and Practitioners

Assess your patient's health promotion and maintenance practices, such as exercise and a healthy diet. Ask about preventive screening tests, such as mammograms and prostate

examinations, and current immunizations, such as the influenza vaccine. Recent newcomers may not have been tested or immunized if they came from less affluent countries where the technology and resources are not available. Other patients may have access to resources but may choose or not be able to follow recommended testing or other health promotion practices.

Determine if your patient is able to afford health care and what type of insurance coverage he or she has. Many people have health insurance through their employer, but if the patient is not employed or is working part-time, he or she may not have that benefit. Collaborate with the case manager or social worker to help find resources to pay for health care.

Another aspect of health care practices that is important to ask about is the use of alternative health care systems and healers. Although many people in the United States use the traditional medical and nursing system for health care, some do not seek professional care for many reasons, such as:

- Transportation difficulties
- High cost of care
- Fear and distrust of health care workers
- Poor communication between patients and professionals

Therefore cultural ways of healing might be sought before or while seeking care from the traditional health care system. Although considered unscientific and strange to many health care professionals, it is essential to assess and support patients in their cultural practices when appropriate.

Many cultures work to preserve both their heritage and their health. Folk health beliefs, practices, and values are learned from experience and observations. They are passed down from generation to generation and have been found to be valuable. For example, acupuncture is an ancient Chinese therapy widely used today. Information about these treatments and other common complementary and alternative therapies is found in [Chapter 2](#). In addition, they are discussed in many interventions chapters as they relate to specific health problems.

Generic and folk systems of caring for and curing people have been around for thousands of years. For example, early ancestors found they could prevent or cure disease with plants. Digitalis (which comes from the foxglove plant) and belladonna have been used for many generations to treat heart failure and tuberculosis. Methods other than plants are also used. There are also numerous hot/cold beliefs related to healing. These beliefs may not necessarily be based on a nurse's definition of temperature. Hot/cold theories of healing are found among Hispanic, Arab, Asian, Southeast Indian, Southern Anglo-American, African-American, and other black cultures. For example, some Hispanic women believe that partaking of "cold" foods and medicines after pregnancy will cause bleeding to stop. They believe this blood is reabsorbed into the body to cause nervousness or insanity later in life. A similar belief is that cold can get into the open vagina after childbirth and stay in the body to cause arthritis in adult life. Health care providers must realize that the patient's view of the cause of the problem may be quite different from the scientific explanation.

The "evil eye" is a prominent belief in some cultures, including Hispanic and Arab cultures. The Spanish term for this belief is *mal de ojo*. Some people believe that "the gods" give the evil eye when they become envious or jealous when

FIG. 4-2 “Hand of God” amulet to protect the wearer from the “evil eye.”

a person is excessively praised or admired. Another belief is that a person who is angry with another person can “put the evil eye” on him or her. Various amulets are worn to reflect the evil eye back onto the person who caused it (Fig. 4-2).

A very important point to consider with folk medicine is the use of particular phrases to describe health problems. Some African Americans and others refer to blood in various ways. For example, “high blood” can mean hypertension, or too much blood in the body, or it can mean the movement of blood to a higher part of the body such as the brain or head. The movement of blood into the head is commonly believed to cause strokes or nervousness or to make the person “fall out” (faint). A similar situation is “low blood,” which can mean low blood pressure or anemia. These

FIG. 4-3 Within the Mexican-American folk medicine system, the *curandero* is the folk healer.

different terms can cause communication problems. When taking care of your patients, ask questions to determine the intended meaning of certain phrases.

Some patients may not seek traditional health care providers, such as physicians and nurse practitioners, as their first source for treatment. Instead, they go to cultural healers, especially in American Indian and some Hispanic cultures. For instance, in the Mexican-American medicine system, the folk healer is called a **curandero** (male) or **curandera** (female). He or she considers health and health care from a holistic, spiritual perspective rather than the traditional scientific viewpoint (Fig. 4-3).

When performing a cultural assessment, be sure to ask your patients whom they consider as their primary source of treatment or healing and what methods they use. Do not be judgmental, and show respect for their values and beliefs at all times. Use an interpreter if you cannot understand their responses.

Culture is a very broad area but an essential aspect of nursing care. Be sure to document your cultural assessment findings for communication with other members of the health care team. For additional information about cultural assessment, review the culture chapter in your fundamentals textbook. For more information about specific cultures, refer to the bibliography resources.

GET READY FOR THE NCLEX® EXAMINATION!

KEY POINTS

Review these Key Points.

- Culture refers to integrated patterns of behavior acquired over time that includes thought, language, beliefs, customs, norms, and ways of life.
- Cultural competence is the ability of health care providers and organizations to understand and respond effectively to the cultural and linguistic needs of patients.
- To assess your cultural competence, answer the questions in Table 4-1.
- One of the major purposes of *Healthy People 2020* is to eliminate differences in health and health care access and focus on public health issues that need improvement.
- Nurses need to be educated in and assess specific cultural practices that affect assessment and planning of patient care, including spirituality, nutrition, and communication (see Table 4-2).
- The homeless population is increasing because of the recession and high unemployment.

GET READY FOR THE NCLEX® EXAMINATION! —cont'd

- The homeless are very prone to cardiovascular disease (CVD), infections, substance abuse, and other mental health disorders.
- Be sure to establish trust with homeless patients and keep the plan of care simple.
- Communication techniques vary among cultural groups and may be misinterpreted; nurses need to learn how groups communicate (verbal and nonverbal) to avoid misperceptions.
- The Joint Commission requires that professional interpreters be available to prevent communication errors with patients and their families.
- Two major issues related to the very diverse LGBT culture are health disparities and the quality of LGBT health care.
- Use the recommendations in [Table 4-3](#) when communicating about sexual identity.
- Dwarfism is a common biologic variation; dwarves are also called *people of short stature* and *little people*.
- Little people have many orthopedic problems that often require surgery. Assess these patients for risk for falling, and be sure they have adaptive resources to help with ADLs.
- Be aware that certain drugs work differently for some patients based on race or ethnicity.
- Be sure to identify and help meet patients' spiritual needs; certified health care chaplains can assist in meeting these needs.
- Patients may avoid the traditional health care system because of transportation problems, high cost of care, fear and distrust of health care staff, or poor communication between patients and health care providers; generic or folk medicine may be used as an alternative.
- Examples of generic and folk medicine are the use of the *curandero* by some members of the Mexican-American culture and the use of clay for healing in some Southeastern and Appalachian people.

Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Identify the role of the nurse as an advocate for patients in acute pain and chronic pain.
2. Explain the importance of collaborating with the health care team in developing the pain management plan of care.

Health Promotion and Maintenance

3. Develop a teaching plan for patients to include complementary and alternative therapies for pain management.
4. Incorporate special considerations for older adults related to pain assessment and management.
5. Describe how to provide patient-centered care by respecting patients' preferences, values, and beliefs regarding pain and its management.

Psychosocial Integrity

6. Discuss the attitudes and knowledge of patients and their families regarding pain assessment and management.

Physiological Integrity

7. Perform a complete pain assessment, and document per agency policy.
8. Differentiate between addiction, pseudoaddiction, tolerance, and physical dependence.
9. Compare and contrast the characteristics of the major types of pain and examples of each.
10. Explain the role of non-opioid analgesics in pain management.
11. Develop a plan of care to prevent common side effects of opioid analgesics.
12. Compare the advantages and disadvantages of drug administration routes.
13. Determine the patient's need for pain medication, including PRN and adjuvant therapy.
14. Prioritize care for the patient receiving patient-controlled analgesia.
15. Outline care for a patient receiving epidural analgesia.
16. Identify the importance of incorporating nonpharmacologic interventions into the patient's plan of care as needed to control pain.

Pain is a universal, complex, subjective experience. It is the most common reason for a patient to seek medical care and the number-one reason for a person to take medication. It alters or diminishes quality of life more than any other single health-related problem. Despite more than 35 years of work by clinicians and professional and lay organizations, unrelieved and undertreated pain remains a

major yet often avoidable public health problem in the world.

The nurse's primary role in pain management is to advocate for the patient by *believing* reports of pain and acting promptly to relieve it, while respecting the patient's preferences and values (Quality and Safety Education for Nurses [QSEN], 2011). Even though some nurses with many

years of experience think that they can identify patients in pain, it is sometimes not easy to do.

In response to mandates by The Joint Commission and other organizations, many hospitals and other health care agencies in the United States have **interdisciplinary pain teams**, also known as **analgesia teams**, who consult with staff and prescribers on how best to control the patient's pain. The team typically consists of one or more nurses, pharmacists, case managers, and physicians. In larger facilities, pain teams may specialize by type of pain (e.g., cancer pain team). Although a large part of the team's plan may center on drug therapy, this group also recommends nonpharmacologic measures as appropriate.

OVERVIEW

Everyone experiences pain at some point in life. Because pain is such a private and personal experience, it may be difficult to describe or explain to others. The amount of pain and responses to it vary from person to person; therefore interpreting pain solely on actions or behaviors can be misleading.

Pain is generally related to some type of tissue damage and serves as a warning signal. Although pain is familiar to most people, it is so complex that there is no single, universal treatment.

Definitions of Pain

Pain is an unpleasant sensory and emotional experience associated with actual or potential tissue damage. In their classic work, McCaffery and Pasero (1999) offered a more personal explanation of pain when they stated that pain is whatever the experiencing person says it is and exists whenever he or she says it does. This understanding of pain requires that the patient be seen as the authority on the pain and as the *only* one who can define the experience. *In other words, self-report is always the most reliable indication of pain.* Nurses who approach pain from this perspective can help the patient achieve effective pain management by advocating for proper control. Of course, if the patient cannot communicate, self-report is not possible. In this case, a variety of methods and observation of nonverbal indicators are used to assess the pain, as described later in this chapter.

Scope of the Problem

Pain is also a major economic problem and a leading cause of disability that hampers the lives of many people, especially older adults. Chronic pain is the most common cause of long-term disability, affecting millions of Americans and others throughout the world.

Pain is not adequately treated in all areas of health care. Populations at the highest risk are older adults, substance abusers, and those whose primary language differs from that of the health care professional. Older adults in nursing homes are especially at risk because of lack of professional staff and communication problems. In patients who are substance abusers, unrelieved pain can contribute to relapses or increased substance use.

Inadequate pain management can lead to many consequences affecting the patient and family members. These consequences often affect the patient's and family's quality of life (Table 5-1). Therefore, as a nurse, you have a legal and

TABLE 5-1 IMPACT OF UNRELIEVED PAIN

Physiologic Impact

- Prolongs stress response
- Increases heart rate, blood pressure, and oxygen demand
- Decreases GI motility
- Causes immobility
- Decreases immune response
- Delays healing
- Increases risk for chronic pain

Quality-of-Life Impact

- Interferes with ADLs
- Causes anxiety, depression, hopelessness, fear, anger, and sleeplessness
- Impairs family, work, and social relationships

Financial Impact

- Costs Americans billions of dollars per year
- Increases hospital lengths of stay
- Leads to lost income and productivity

TABLE 5-2 CHARACTERISTICS OF ACUTE PAIN AND CHRONIC PAIN

ACUTE	CHRONIC* (OR PERSISTENT)
• Has short duration • Usually has a well-defined cause • Decreases with healing • Is reversible • Serves a biologic purpose (warning sign) • Ranges from mild to severe intensity • May be accompanied by anxiety and restlessness	• Lasts longer than 3 months • May or may not have well-defined cause • Begins gradually and persists • Is exhausting and serves no biologic purpose • Ranges from mild to severe intensity • May be accompanied by depression and fatigue, as well as decreased functional ability

*Includes chronic cancer pain and chronic non-cancer pain.

ethical responsibility to ensure that patients receive adequate pain control. In 2000, The Joint Commission (TJC) published pain standards approved by the American Pain Society. TJC states that patients in all health care settings, including home care, have a right to effective pain management.

Patients rely on nurses and other health care professionals to adequately assess and manage their pain. As the coordinator of patient care, be sure to accurately document your assessments and actions, including patient and caregiver teaching.

Categorizing Pain

Pain can be categorized in two ways: by type related to the characteristics of the pain (Table 5-2) or by the physiologic source of the pain. The two major types of pain are acute and chronic. *Acute pain* often results from sudden, accidental trauma (e.g., fractures, burns, lacerations) or from surgery, ischemia, or acute inflammation. *Chronic pain* or *persistent pain* is further divided into two subtypes. **Chronic cancer pain** is pain associated with cancer or another progressive disease such as acquired immune deficiency syndrome (AIDS). The cause of pain is usually life threatening. **Chronic non-cancer pain** is associated with tissue injury that has healed or is not associated with cancer, such as arthritis or chronic back pain. This type of pain is the most common.

Acute Pain

Almost everyone experiences acute pain at some time. The major distinction between acute pain and chronic pain is the effect on biologic responses. **Acute pain** serves a biologic purpose. It acts as a warning signal by activating the sympathetic nervous system and causing various physiologic responses. These responses are similar to those found in “fight-or-flight” reactions and include:

- Increased heart rate
- Increased blood pressure
- Increased respiratory rate
- Dilated pupils
- Sweating

Behavioral signs of acute pain may include restlessness (especially among older adults), an inability to concentrate, apprehension, and overall distress.

Acute pain is usually temporary, has a sudden onset, and is easily localized. The pain is typically confined to the injured area and may subside with or without treatment. As the injured area heals, the pain sensation changes. Although possibly severe, acute pain is limited over time and generally can be managed successfully. Both the caregiver and the patient can see an end to the pain, which makes coping somewhat easier.

Pain that accompanies surgery is one of the most common examples of acute pain, but it is not always well managed. Usually, poorly managed postoperative pain is a result of inadequate drug therapy.

The severity of postoperative pain may be a predictor of long-term pain. The use of **preemptive analgesia** is a technique designed to decrease pain in the postoperative period, decrease the requirements for a postoperative analgesic, prevent morbidity, and decrease hospital stay. Preemptive analgesia includes administering local anesthetics, opioids, and other drugs in the preoperative, intraoperative, and/or postoperative period. This intervention may inhibit changes in the spinal cord—changes that can lead to a central sensitization that results in chronic pain.

In general, intrathoracic and upper intra-abdominal surgical approaches are associated with more severe, steady wound pain and with pain on movement after surgery. Many patients who undergo superficial surgery of the head and neck, chest wall, or limbs report minimal postoperative pain. Muscle-splitting procedures, like thoracotomy, are generally far more painful than muscle-stretching procedures, such as open hysterectomy. Patients who have joint replacements for severe arthritic pain often report less pain after surgery than before surgery because the damaged joint cartilage has been removed.

Chronic Pain

Chronic pain or **persistent pain** is often defined as pain that lasts or recurs for indefinite periods, usually for more than 3 months. The onset is gradual, and the character and quality of the pain change over time. Because chronic pain often involves deep body structures, it is usually poorly localized (hard to pinpoint) and often difficult to describe. If the underlying cause cannot be treated, controlling the long-term effects of chronic pain may be a difficult clinical challenge.

Because chronic pain persists for extended periods, it can interfere with personal relationships and ADLs. It can also result in emotional and financial burdens. Some patients feel

depressed and hopeless because of uncontrolled chronic pain and its consequences. *Although many characteristics of chronic pain are similar in different patients, be aware that each patient is unique and requires a highly specialized plan of care.*

Chronic Cancer Pain. Most patients with advanced cancer have moderate to severe pain. What is frustrating is that we have known for over 30 years that 90% of cancer pain can be successfully managed by giving adequate amounts of oral opioids around the clock. Yet patients with terminal cancer are often inadequately treated for their excruciating pain.

Most cancer pain is caused by the disease itself. The sources of pain include nerve compression, invasion of tissue, and/or bone metastasis, an extremely painful condition. Cancer treatments also can cause pain (e.g., from surgery and toxicities from chemotherapy and radiation therapy).

Patients with cancer pain generally have pain in two or more areas but usually talk about only the primary area of pain. Be sure to perform a complete pain assessment to ensure an effective plan of care (see the Concept Map on p. 42).

Chronic Non-Cancer Pain. Chronic non-cancer pain is an even larger global health problem, occurring most often in people older than 65 years. *Unlike acute pain, chronic pain serves no biologic purpose.* After the initial warning signal of pain, the body must learn to adapt to the persistent pain impulses by blocking or adjusting to sympathetic nervous system response (which causes the fight-or-flight reaction in acute pain). Because of this adaptation, the symptoms often associated with acute pain, such as increased pulse, are *absent* with chronic pain.

Chronic non-cancer pain was formerly called *chronic non-malignant pain*. However, most pain experts, and certainly patients who suffer with daily pain, believe that all pain is malignant—thus the newer term. Chronic non-cancer pain may be caused by chronic diseases such as rheumatoid arthritis, back injuries, and fibromyalgia.

Pain is also categorized as either nociceptive (normal processing of pain) or neuropathic (abnormal pain processing). **Nociceptive pain** is either visceral or somatic (Table 5-3). **Somatic pain** arises from the skin and musculoskeletal structures, and **visceral pain** arises from organs. **Neuropathic pain** is one of the most challenging types of chronic non-cancer pains; it results from some type of nerve injury. Neuropathic pain is still not completely understood. It is divided into centrally or peripherally generated pain. Regardless of the cause, neuropathic pain is described as burning (most common), shooting, stabbing, and feeling “pins and needles.”

Theoretical Bases for Pain

Pain Transmission

Painful stimuli often originate in the periphery (extremities) of the body. To be perceived, the stimuli must be transmitted first to the spinal cord and then to the central areas of the brain. If the pain impulse is not transmitted to the brain, the person feels no pain. In the periphery, two specific fibers can transmit stimuli: (1) A delta fibers, which are found primarily in the skin and muscle; and (2) C fibers, which are distributed in muscle, periosteum, and viscera. Both of these nerve fibers are capable of accepting nociceptive stimuli.

A delta fibers are myelinated fibers that carry rapid, sharp, pricking, or piercing sensations. A person feeling these sensations can generally localize them readily to a fairly

Concept Map: Chronic Cancer Pain

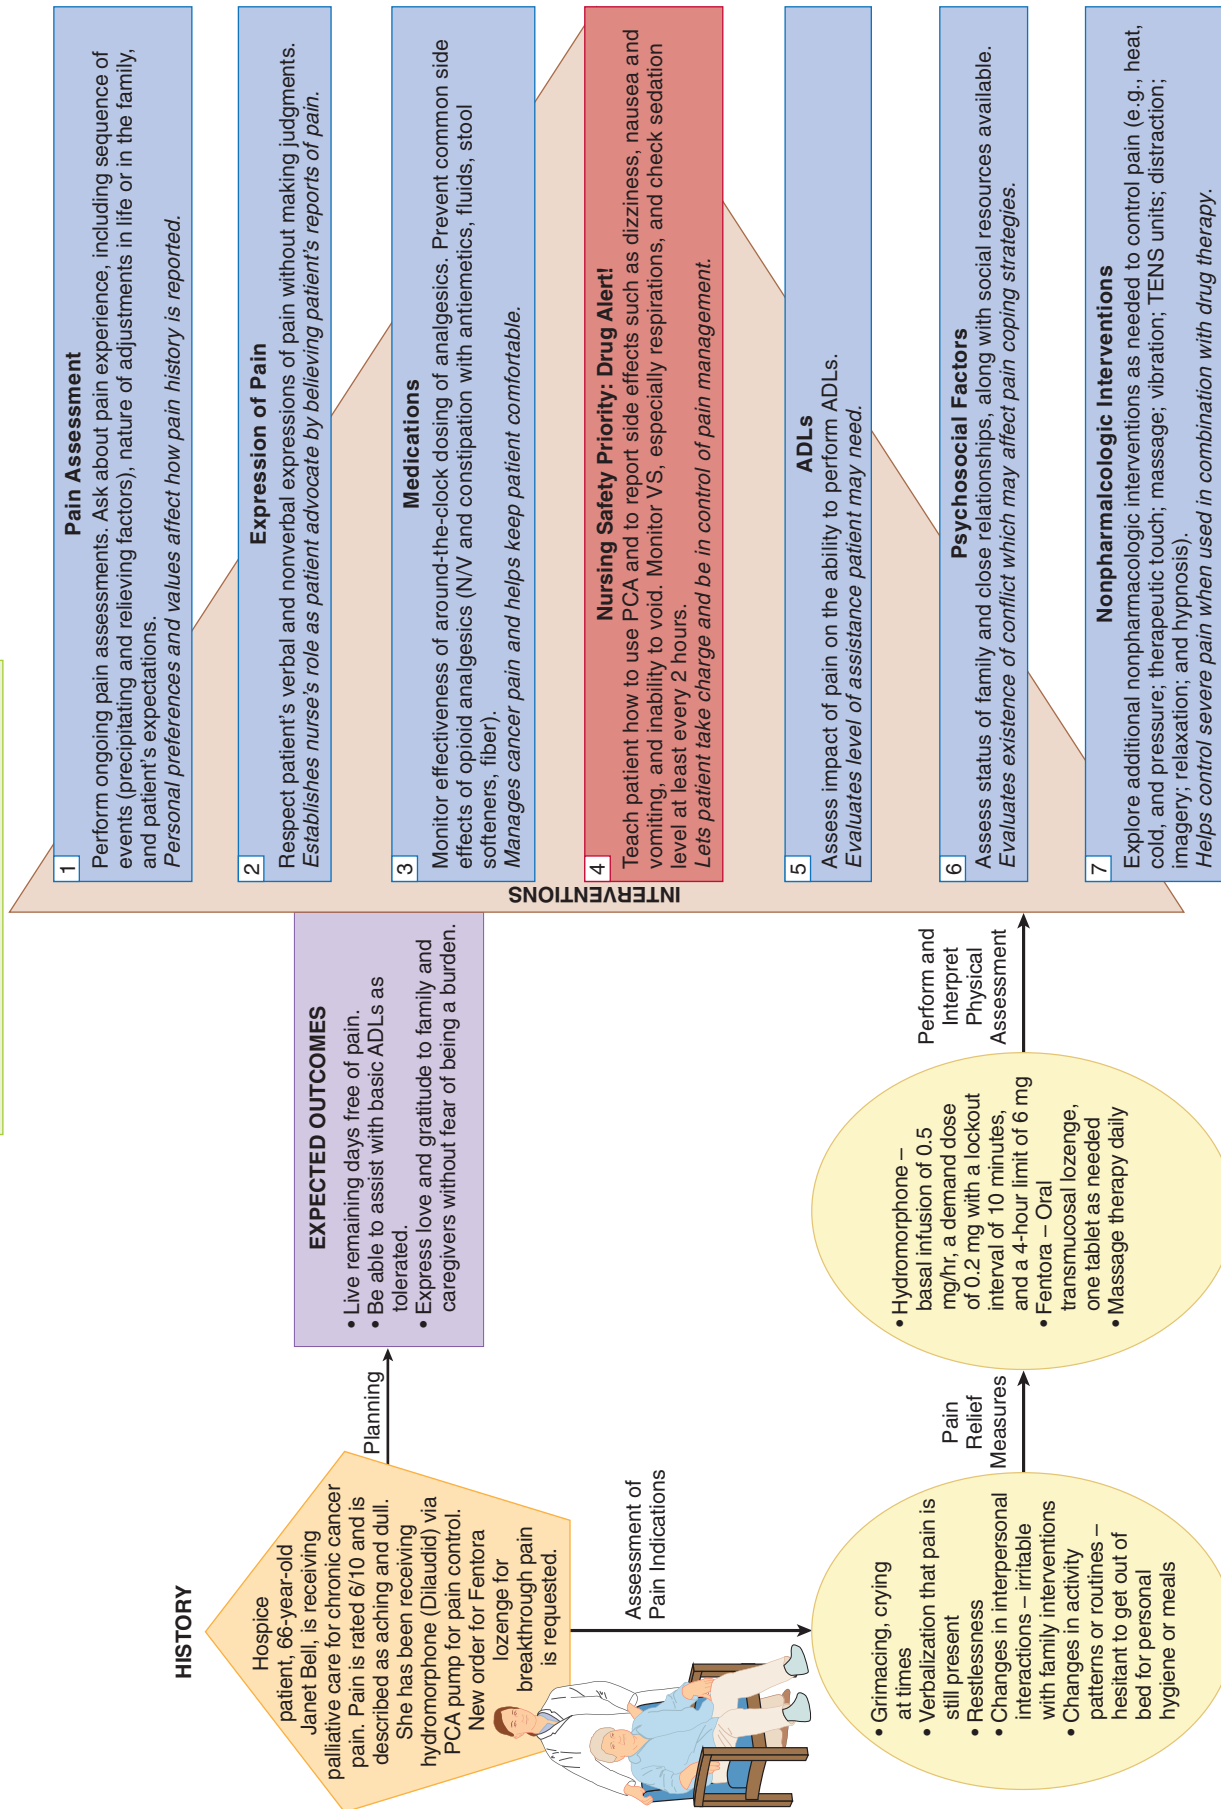

TABLE 5-3 PHYSIOLOGIC SOURCES OF PAIN

PHYSIOLOGIC STRUCTURE	CHARACTERISTICS OF PAIN	SOURCES OF ACUTE POSTOPERATIVE PAIN	SOURCES OF CHRONIC PAIN SYNDROMES
Nociceptive Pain			
Somatic Pain			
Cutaneous or superficial: skin and subcutaneous tissues	Sharp, burning	Incisional pain, pain at insertion sites of tubes and drains, wound complications, orthopedic procedures, skeletal muscle spasms	Bony metastases, osteoarthritis and rheumatoid arthritis, low back pain, peripheral vascular diseases
Deep somatic: bone, muscle, blood vessels, connective tissues	Dull, aching, cramping		
Visceral Pain			
Organs and the linings of the body cavities	Poorly localized Diffuse, deep cramping or splitting, sharp, stabbing	Chest tubes, abdominal tubes and drains, bladder distention or spasms, intestinal distention	Pancreatitis, liver metastases, colitis, appendicitis
Neuropathic Pain			
Nerve fibers, spinal cord, and central nervous system	Poorly localized Shooting, burning, fiery, shocklike, sharp, painful numbness	Phantom limb pain, postmastectomy pain, nerve compression	HIV-related pain, diabetic neuropathy, postherpetic neuralgia, chemotherapy-induced neuropathies, cancer-related nerve injury, radiculopathies

HIV, Human immune deficiency virus.

well-defined area. Because these fibers respond mainly to mechanical rather than chemical or thermal stimuli, they are called *mechanical nociceptors*.

C fibers are unmyelinated or poorly myelinated fibers that conduct thermal, chemical, and strong mechanical impulses. Pain conduction from C fibers is slow, more diffuse (widespread) and dull, burning, or achy—quite different from the sensations of A delta fibers. In contrast to the intermittent nature of A delta sensations, C fibers usually produce persistent pain.

Although many theories of pain have been discussed, the classic **gate control theory** by Melzack and Wall (1982) still forms the basis of what is believed by most pain researchers today. According to this theory, a gating mechanism occurs in the spinal cord. Nerve fibers (A delta and C fibers) transmit pain impulses from the periphery of the body. These impulses travel to the dorsal horn of the spinal cord, specifically to the *substantia gelatinosa*, where the gating mechanism occurs. When the gate is opened, pain impulses ascend to the brain; when the gate is closed, the impulses do not get through and pain is not perceived (Fig. 5-1).

Morphine-like substances called **endorphins** are released when the large-diameter nerve fibers are stimulated. These fibers close the gate and decrease pain transmission. This helps explain why many noninvasive pain management techniques work to relieve pain. Endorphins are thought to be a gene product, and producing them requires a stimulus to the brain.

Similar gating mechanisms exist in the nerve fibers descending from the thalamus and cerebral cortex. These areas of the brain regulate thoughts and emotions, including beliefs and values. When pain occurs, a person's thoughts and emotions can modify one's perceptions as they reach the level of conscious awareness.

The gate control theory has helped nurses and other health care professionals recognize the *holistic* nature of

pain. As a result, many cognitive-behavioral therapies (e.g., imagery and distraction described on p. 60) are used to help relieve pain.

Attitudes and Practices Related to Pain

The attitudes of health care professionals toward pain influence the way they perceive and interact with patients in pain. Without adequate assessment skills or knowledge of pain and analgesic therapy, they may not be able to understand their patients' pain.

Nurses who have little personal experience with pain may not appreciate the scope of painful conditions associated with diseases and medical or surgical interventions. They may expect patients with chronic pain to react similarly to those with acute pain. Nurses may assume that reactions to pain fall within a certain norm based on their own cultural values. The more that a patient's response varies from these expected norms, the more likely that a nurse's attitude toward the patient will be positively or negatively biased.

Not only do health care professionals need continued education about pain management, but the public needs education as well. Nurses can help patients and their families achieve and maintain successful pain management through education.

Many patients are reluctant to report pain. When they do, they may underreport its severity. Patients may not share their existence of pain because they want to be "good" patients or do not want to bother or distract their caregivers from other issues in their care. In patients with a history of cancer, pain can be an unwanted reminder of the disease and its progression.

Some patients are also reluctant to take pain medications, especially opioid analgesics, because they fear becoming addicted to or used to the drug, especially older adults. Educate patients and reassure them that these drugs are not likely to cause addiction in those having pain.

FIG. 5-1 The gate control theory of pain.

Pain Perception

Many variables affect the perception of and response to pain. Factors such as age, gender, sociocultural background, and genetics influence the patient's ability to process and react to pain. These factors also put patients at risk for undertreatment.

Certain painful conditions are more common in either men or women. Most chronic pain sufferers are women. Women have more migraine headaches, tension headaches, rheumatoid arthritis and osteoarthritis, fibromyalgia, and multiple sclerosis. Men have more cluster headaches, back pain, gout, peripheral vascular disease, and postherpetic neuralgia.

CONSIDERATIONS FOR OLDER ADULTS

Age can influence how pain is perceived, assessed, and treated. It has been well documented that the incidence of pain in older adults is high, as is risk for undertreatment. [Chart 5-1](#) addresses special considerations for assessing and managing pain in older adults.

Addiction, Pseudoaddiction, Tolerance, and Physical Dependence

It is crucial that nurses and other health care professionals not label a patient as an "addict," "clock-watcher," or "drug seeker." These labels have caused biases and have a negative impact on the patient-nurse relationship.

In their classic position statement, the American Society for Pain Management Nursing (ASPMN) states that **addiction** is (ASPMN, 2002):

... a primary, chronic neurobiologic disease with genetic, psychosocial, and environmental factors influencing its development and manifestations. It is characterized by behaviors that include one or more of the following: impaired control over drug use, compulsive use, continued use despite harm, and craving. (p. 1)

Addiction occurs over a long time—not as a result of one hospital stay or treatment for one episode of acute pain.

The danger of addiction to pain medication is vastly overrated. Although available data on addiction consistently show that it is rarely a result of using opioids for pain relief, health care professionals still have exaggerated fears. Patients and families also have fears related to addiction. Carefully explain the difference between physical dependence and addiction whenever a patient starts on opioid therapy.

Pseudoaddiction is (ASPMN, 2002):

... an iatrogenic syndrome created by the undertreatment of pain. It is characterized by patient behaviors such as anger and escalating demands for more or different medications, and results in suspicion and avoidance by staff. (p. 1)

Pseudoaddiction can be distinguished from true addiction in that the behaviors resolve when pain is effectively treated.

Tolerance is (ASPMN, 2002):

... a state of adaptation in which exposure to a drug induces changes that result in a decrease in one or more of the drug's effects over time. (p. 1)

Some of these changes include increasing drug excretion and reducing the number of receptors to bind the drug. Many advanced cancer patients find that they need increasing doses of opioids to control their pain.

Physical dependence is the (ASPMN, 2002):

... adaptation manifested by a drug-class-specific withdrawal syndrome that can be produced by abrupt cessation, rapid dose reduction, decreasing blood level of the drug, and/or administration of an antagonist. (p. 1)

A person who is drug tolerant, however, does not experience withdrawal, even when the drug is stopped suddenly.

Physical dependence occurs in *everyone* who takes opioids over a period of time. *It is important to prevent physical withdrawal.* So-called **withdrawal** or **abstinence syndrome** results when a patient who is physically

CHART 5-1 NURSING FOCUS ON THE OLDER ADULT

Pain**Prevalence of Pain**

- Recognize that older adults are at great risk for undertreated pain.
- Consider the older adult at risk for the undertreatment of cancer pain because of inappropriate beliefs about pain sensitivity, tolerance, and ability to take opioids.

Beliefs About Pain

- In addition to receiving less analgesia, older adults tend to report pain less often than do younger adults. These findings may be related to beliefs and concerns about pain and the reporting of pain. Many older people hold these beliefs and concerns about pain:
 - Pain is something that must be lived with.
 - Expressing pain is unacceptable or is a sign of weakness.
 - Reporting pain will result in being labeled as a “bad” patient.
 - Nurses are too busy to listen to reports of pain.
 - Pain signifies a serious illness or impending death.
- Nurses should be aware of the beliefs of older patients regarding pain management. Nurses and other caregivers often undermedicate these patients and are sometimes reluctant to administer the prescribed analgesics.

Assessment

- Ask about present pain only; ask the patient to assess his or her pain whenever possible.
- Ask the patient’s family or other caregiver whenever the patient cannot respond appropriately.
- Document using a standard behavioral pain assessment scale.
- Explain the scale each time it is used.
- Use verbal descriptions such as “ache,” “sore,” and “hurt,” *rather than the word “pain.”*
- Use visual representations of pain measures rather than mental images of pain rating scales. Be sure that the patient is wearing glasses and hearing aids if needed and available.

- Alter a written pain scale to include large lettering, adequate space between lines, non-glossy paper, and color for increased visualization.
- Provide adequate lighting and privacy to avoid distracting background noise.

Considerations for Cognitively Impaired Patients

- Assess for nonverbal indicators of pain (facial expressions, grimacing, vocalizations, body movements, behavioral changes).
- Remember to “assume pain is present” (APP) in cognitively impaired patients with diseases and conditions commonly associated with pain.

Management of Pain

- Use around-the-clock dosing of analgesics.
- Consider an analgesic trial in a cognitively impaired patient.
- Beware of adverse effects of acetaminophen (hepatotoxicity, nephrotoxicity) and NSAIDs (GI bleeding, nephrotoxicity).
- Start low and go slow with drug dosing, especially opioids.
- Avoid the use of meperidine, codeine, and propoxyphene (available in combination with acetaminophen, as Darvocet).
- Do not give meperidine to older adults and those with renal disease because of the prolonged half-life of its drug metabolite *normeperidine*.
- Use non-drug pain relief measures or adjuvant drugs as appropriate.
- To promote drug adherence, suggest using a pillbox to organize each day’s medications.
- Teach the patient and family or other caregiver about the drug regimen and when to notify the primary care provider if adverse drug effects occur.

dependent on opioids abruptly ceases using them. *Abstinence syndrome may also occur if a patient on opioids receives a reversal agent, such as naloxone (Narcan).* These symptoms result from autonomic nervous system responses and include nausea and vomiting, abdominal cramping, muscle twitching, profuse perspiration, delirium, and convulsions. When necessary to discontinue opioid analgesia for a patient who is opioid dependent, a slow tapering (weaning) of the drug dosage lessens or alleviates the physical withdrawal symptoms. Doses of opioids should be tapered by 10% to 20% daily for patients on chronic opioid therapy. Clonidine (Catapres, Dixarit ) may be used to help alleviate the distressing symptoms of withdrawal in younger adults. It should not be given to older adults because of its side effects.

Although tolerance, physical dependence, and addiction are different conditions, they may coexist. However, it is important to distinguish tolerance and physical dependence from addiction.

Patients who are substance abusers often have traumatic injuries and other health problems that cause pain. Keep in mind that substance abusers, typically those abusing opioids, are often tolerant to the pain-relieving effects of opioid analgesics and generally require increased doses. Abrupt physiologic withdrawal is always a danger when recreational users of opioid agonists are given mixed agonist-antagonists and partial agonists.

The clinical use of placebos in non-research-based therapies has not been shown to have a sustained effect on pain relief. A **placebo** is any medical treatment or nursing care that produces an effect in a patient because of its therapeutic intent and not because of its actual physical or chemical properties. When a patient responds favorably to a placebo, it is known as the **placebo effect**. Placebos do not indicate whether or not a patient has real pain.

! NURSING SAFETY PRIORITY**Drug Alert**

Because of the deception involved and the need for informed consent, never administer a placebo to your patient.

As required by most health care accrediting or regulatory agencies, health care agencies have developed programs to educate professionals about pain management, including the inappropriate use of placebos. Because of The Joint Commission’s commitment to effective pain control, a policy against the use of placebos is recommended to be in place in all accredited institutions and agencies. The American Society for Pain Management Nursing (ASPMN) has a position statement available on the website against the use of placebos for the management of pain (ASPMN, 2010).

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

History

The American Pain Society refers to pain as the *fifth vital sign*. Like for vital signs, health care agencies require initial and ongoing pain assessments. Begin by asking the patient about the:

- Pain experience, including the sequence of events (precipitating and relieving factors)
- Nature of adjustments, if any, in life or in the family
- Beliefs about the cause of the pain and what should be done about it (patient's expectations)

Remember that the patient's personal preferences and values affect how he or she reports the pain history. When culturally appropriate, be sure to include families and significant others in this information-gathering process to be family-centered.

Patients may report pain in the absence of any observable or documented physiologic changes. To be patient-centered, respect the patient's verbal and nonverbal expressions of pain without making judgments or inferences about the reality of the pain. If patients perceive that health care professionals doubt the existence of their pain, mistrust and other negative feelings can arise and interfere with a therapeutic nurse-patient relationship.

Assess the length of time the patient has experienced pain. Patients may welcome an opportunity to discuss acute pain with the nurse because it is a relatively short-term experience and is easily described. However, those with chronic pain can become frustrated when they are unable to adequately describe their often vague and diffuse pain experience. Structured interviews using assessment aids (e.g., pain scales, descriptors) often help patients express their pain.

Information about a person's pain can be helpful in understanding the factors associated with the present pain or previous episodes of pain. If the patient is in pain when you are obtaining the history, keep the session reasonably short or continue later. Essential data include:

- **Precipitating factors.** Does the person associate any activities, food, or other environmental factors with the onset of pain? What does the patient think causes the present pain? Was the onset of pain sudden or slow? Has the patient done anything or taken anything to relieve the pain? What were the results of the intervention?
- **Aggravating factors.** What factors make the pain worse? What influence has this pain had on the patient's activity? What lifestyle changes have been affected (e.g., diet, job, sleep)?
- **Localization of pain.** Can the person localize the pain or describe where it travels or radiates?
- **Character and quality of pain.** What words does the patient use to describe the pain and its character, quality, or intensity?
- **Duration of pain.** How long has the patient experienced this pain?

Physical Assessment/Clinical Manifestations

People with *acute pain* may have physiologic changes, such as tachycardia and blood pressure changes. Blood pressure is

usually increased initially and then decreased. However, not all patients with acute pain have these signs, so *his or her statement of pain is the only reliable indicator*.

A person with *chronic pain* usually adapts to these physiologic changes as the body attempts to compensate for and adapt to noxious stimuli. The pain no longer serves as a necessary warning. Patients with chronic pain, then, often develop coping skills and may appear to look quite well.

Certain motor or body movements may be associated with either acute or chronic pain. Some may be more exaggerated or obvious than others. Patients in pain may support or shield ("splint"), holding painful body parts while moving, or they may lie listlessly because they are afraid to move. Assess the functional status and degree of impairment in the patient with pain.

The mnemonic **PQRST** may be helpful in organizing the pain assessment (Jarvis, 2012):

P: Precipitating or palliative. What brings it on? What makes it better? Worse? When did you first notice it?

Q: Quality or quantity. How does it look, feel, or sound? How intense/severe is it?

R: Region or radiation. Where is it? Does it spread anywhere?

S: Severity scale. How bad is it (on a scale of 1 to 10)? Is it getting better, worse, or staying the same?

T: Timing. Onset—Exactly when did it first occur? Duration—How long did it last? Frequency—How often does it occur?

Location of Pain. Assess the level and location of pain. If oriented, most patients can usually describe the severity of acute pain or chronic pain. The actual area or location of the pain, however, may not be as easily identified. Ask the patient whether the pain is superficial or deep. In general, those with pain involving superficial or cutaneous (skin) structures describe their pain as superficial and can often localize the pain to a specific area.

Pain may be described as belonging to one of four categories related to its location:

- **Localized pain** is pain confined to the site of origin.
- **Projected pain** is pain along a specific nerve or nerves.
- **Radiating pain** is diffuse pain around the site of origin that is not well localized.
- **Referred pain** is pain perceived in an area distant from the site of painful stimuli.

Ask the patient who has difficulty specifying the exact location of pain to point to the painful areas on his or her own body or on another person. If the patient is able to communicate, have him or her point to or shade in the painful areas on a diagram of the front and back of the human body (Fig. 5-2). Encourage those who cannot identify the painful areas and state that they just "hurt all over" to focus on parts of the body that are not painful. Ask the patient to concentrate on different body parts, beginning with the hand and fingers of one extremity, and identify the presence or absence of pain. By focusing attention on selected areas of the body, the patient is assisted in localizing painful areas. People who state that they hurt everywhere often begin to realize that some parts of the body are not painful.

Patients may present with more than one specific painful site. Identifying painful areas helps the patient understand the origin of the pain. This understanding is particularly

McGill-Melzack PAIN QUESTIONNAIRE Patient's name _____ Age _____ File No. _____ Date _____ Clinical category (e.g., cardiac, neurologic) _____ Diagnosis: _____ _____ _____ Analgesic (if already administered): 1. PAIN INTENSITY SCALES

PAIN RELIEF SCALES

¹If used as a graphic rating scale, a 10-cm baseline is recommended.

²A 10-cm baseline is recommended for VAS scales.

FIG. 5-3 Pain rating scales and pain relief scales.

important for those with cancer, because every new pain often raises the suspicion of metastasis (spread of disease). The pain may have other causes, such as immobility or constipation.

Intensity and Quality of Pain. After asking the patient to locate the pain, ask him or her to describe it. He or she may use one word or a group of words to convey the sensations or feelings of the pain. *Avoid suggesting descriptive words for the pain.*

Subjective measurements of pain intensity are more reliable and accurate than observable qualities of pain. Only the patient can determine the amount or severity of pain being experienced. Various visual analog scales (VASs), number rating scales (NRSs), descriptive word scales, and other measures have been designed to help patients communicate the magnitude or severity of pain and to help nurses quantify the pain (Fig. 5-3).

Use pain intensity scales to measure pain in the clinical or home setting and to assess and determine the effectiveness of pain relief interventions. For most pain scales, the patient is

asked to rate the amount of painful stimuli. Patients with more than one discrete painful site may wish to specify their pain levels by location. Some scales also assess the emotional aspect of pain. Be sure to use the *same* scale over time for the patient, and assess pain intensity both with and without activity.

Verbal descriptive scales typically group words such as “none,” “moderate,” or “severe” and permit an intensity rating of pain. However, the 0-to-10 or 1-to-10 NRS is used most commonly in clinical practice for adult patients who can communicate in English (see Fig. 5-3). For culturally diverse patients with language barriers, the Wong-Baker FACES Pain Rating Scale (pain rating scale of smile to frown) may be helpful. This scale is also used for children, older adults, and developmentally disabled populations (Flaherty, 2008).

Assessing Pain in Cognitively Impaired or Critically Ill Nonverbal Patients. Although it seems obvious, nonverbal, intubated, and cognitively impaired patients do feel pain! It is important to be proactive and assume pain is present, or “APP.”

In 2006, the American Society for Pain Management Nursing published its classic position statement on evidence-based recommendations when performing pain assessments for nonverbal patients (Herr et al., 2006). Five general recommendations for pain assessment were presented:

- Use self-report (when possible).
- Search for potential causes of pain.
- Observe patient behaviors.
- Recognize the value of surrogate reporting (e.g., family member or life partner).
- Attempt an analgesic trial.

Nurses and other clinicians have recently been researching assessment tools to measure observable nonverbal behaviors that indicate the patient is in pain. A variety of valid and reliable tools are published in the literature (Federico, 2009). Most of them are designed to be used for patients with severe dementia. Examples of commonly used assessment tools that can be used for patients with acute confusion or dementia include:

- Pain Assessment Tool for Confused Older Adults (used for hospitalized patients)
- Pain Assessment in Advanced Dementia Scale (PAINAD)
- Discomfort in Dementia of the Alzheimer's Type Scale
- Faces, Legs, Activity, Crying and Consolability Tool
- Non-Communicative Patient's Pain Assessment Instrument (NOPPAIN)
- Checklist of Nonverbal Pain Indicators

The Checklist of Nonverbal Pain Indicators is based on the work of The American Geriatrics Society (AGS) Panel on Persistent Pain in Older Persons. The panel found six common pain indicators that you can observe and document to indicate pain (AGS, 2002):

- Facial expression (e.g., grimacing, crying)
- Verbalizations or vocalizations (e.g., screaming)
- Body movements (e.g., restlessness)
- Changes in interpersonal interactions
- Changes in activity patterns or routines
- Mental status changes (e.g., confusion, increased confusion)

NCLEX EXAMINATION CHALLENGE

Health Promotion and Maintenance

An older woman is admitted to the unit after her emergency abdominal surgery on PCA morphine. She has early Alzheimer's disease and is attempting to pull out her IV line. What is the first method the nurse will use to assess this client's pain level?

- Ask her family or caregiver what they think her pain level is.
- Ask the client what her pain level is.
- Observe her body movements and facial expression.
- Assume she has pain and give her a bolus of PCA morphine.

Psychosocial Assessment

All pain holds significant meaning for the person experiencing it. Patients having *acute pain* from surgery may interpret their pain as necessary and expected. It may be viewed with relief as a sign that some greater problem has been resolved or alleviated by the surgery. Knowing that the duration of the pain is limited may allow the patient to deal with unpleasant sensations without too much difficulty. In contrast, acute chest pain associated with angina may mark the beginning of a life of fear and uncertainty.

Various psychosocial factors influence *chronic pain*. Some factors are similar to those found in the acute pain experience, such as anxiety or fear related to the meaning of the pain. Because chronic pain persists or is perhaps only partially relieved, the patient may feel powerless, angry, hostile, or desperate. He or she is also vulnerable to labels such as "chronic complainer" or "fake." *Remain objective, and advocate for proper pain control for all patients.*

Assess the status of family and other close relationships, along with the range of social resources available to the patient with chronic pain. The existence of a pain-specific conflict with a spouse or significant other may affect or limit pain coping strategies. Other people may react to chronic pain with depression, social withdrawal, and preoccupation with physical symptoms.

If the chronic pain is associated with a progressive disease such as cancer, rheumatoid arthritis, or peripheral vascular disease, the patient may have worries and concerns about the consequences of the illness. People with cancer-related pain may fear death or body mutilation. Some may think they are being punished for some wrongdoing in life. Others may attach a religious or spiritual significance to lingering pain.

Ask open-ended questions (e.g., "Tell me how your pain has affected your job or role as a mother.") to allow the patient to describe personal attitudes about pain and its influence on life. This opportunity can help someone whose life has been changed by pain. However, some patients choose not to share their private information or fears. As a patient-centered nurse, you should respect their preferences and values. Assess the impact of the pain on ability to function. Is the patient able to perform ADLs independently, or is assistance needed?

INTERVENTIONS

Interventions for managing pain are individualized with consideration of the patient's preferences and values. Drug therapy and/or nonpharmacologic interventions are used by nurses and the interdisciplinary health care team.

Drug Therapy

Drug therapy is commonly added for pain control if nonpharmacologic methods are not helpful. The type of drug, how it is administered, and when it is given depend on the type, intensity, and quality of the pain. For example, patients with painful chronic conditions such as arthritis, osteoporosis, cancer, pressure ulcers, and contractures should receive a trial of around-the-clock analgesics, particularly if they are cognitively impaired or cannot communicate. Elliott and Horgas (2009) found that an analgesic trial with acetaminophen reduced pain in community older adults with dementia (see the [Evidence-Based Practice box](#) on p. 50).

Remember to give analgesics before painful procedures such as suctioning, drain removal, and wound care (especially bedside surgical débridement and complex dressing changes). Be sure to plan adequate time for the drugs to take effect so that the patient will be comfortable.

Three groups of drugs can be used to manage pain: non-opioids, opioids, and adjuvants. To advocate for your patient, a thorough understanding of the drugs used to treat pain is necessary (Table 5-4).

Non-Opioid Analgesics. The non-opioid analgesics are the first-line therapy for mild to moderate pain. The two most

EVIDENCE-BASED PRACTICE

Does an Analgesic Trial Decrease Pain in Older Adults with Dementia Who Live in the Community?

Elliott, A.F., & Horgas, A.L. (2009). Effects of an analgesic trial in reducing pain behaviors in community-dwelling older adults with dementia. *Nursing Research*, 58, 140-145.

Older adults who have dementia often cannot verbalize the quality and intensity of their pain. A few studies have examined the use of an around-the-clock analgesic trial for demented older adults in nursing homes. However, none have focused on older adults in the community.

The authors used a within-subjects alternating (ABAB) withdrawal research design to determine if a trial of extended-release acetaminophen (given every 8 hours) would relieve the subjects' pain. Three Caucasian subjects who met specific study criteria were followed daily for 24 days. Two nontreatment (baseline) phases were alternated with two treatment phases to observe the effect of the drug on pain-related behaviors. Pain behaviors were measured during a daily videotaped activity-based protocol designed to elicit pain. The results showed that

pain behaviors decreased during the treatment phases in both frequency and duration.

Level of Evidence: 4

Although the study sample was small, it is an appropriate size for an ABAB research design in which the subjects undergo periods of treatment and nontreatment, a type of quasi-experimental study.

Commentary: Implications for Practice and Research

This study suggests that around-the-clock analgesia using acetaminophen every 8 hours would decrease pain behaviors among older adults with dementia who live in the community. Managing pain for cognitively impaired patients is a challenge, especially for older adults with arthritic pain. Larger studies need to be conducted to investigate analgesic trials in other racial and ethnic groups because the sample in this study was Caucasian.

TABLE 5-4 COMMON EXAMPLES OF ANALGESICS BY CLASSIFICATION

NON-OPIOIDS	ADJUVANTS
Acetaminophen (Tylenol)	Serotonin-norepinephrine reuptake inhibitors (SNRIs):
NSAIDs (nonselective):	Duloxetine (Cymbalta)
Aspirin	Venlafaxine (Effexor)
Ibuprofen (Motrin)	Antiepileptic drugs (AEDs):
Naproxen (Naprosyn)	Gabapentin (Neurontin)
Ketoprofen (Toradol, Orudis)	Pregabalin (Lyrica)
NSAIDs (selective):	Valproic acid (Depakene)
Celecoxib (Celebrex)	Topiramate (Topamax)
OPIOIDS	Muscle relaxants/antispasmodic drugs:
Pure agonists:	Cyclobenzaprine (Flexeril)
Morphine (MS Contin, Kadian, Roxanol, Duramorph)	Baclofen (Lioresal)
Fentanyl (Duragesic, Actiq, Fentora)	Alpha-2 adrenergics:
Hydrocodone (Vicodin)	Tizanidine (Zanaflex)
Oxycodone (OxyContin, Percodan [also contains aspirin])	Local anesthetics/analgesics:
Hydromorphone (Dilaudid, Hydromorph)	Mexiletine (Mexitol)
Methadone	Lidocaine patch (Lidoderm)
Codeine	Diclofenac patch (Flector)
	NMDA antagonists:
	Ketamine
	Dextromethorphan
	Cannabinoids (cannabis extracts)

NMDA, N-methyl-D-aspartate.

common non-opioids are acetylsalicylic acid (aspirin) and acetaminophen (Tylenol). The analgesic effects are the same in equal doses. The single optimal dose of aspirin or acetaminophen is between 650 and 1000 mg.

The analgesic effect of these non-opioids has a ceiling. In other words, if the dose of the non-opioid analgesic is greater than 1000 mg, there will be no additional analgesic effect—only more side effects. Many people underestimate the effectiveness of non-opioid analgesics, also referred to as *peripheral-acting analgesics*. For mild pain, the non-opioids aspirin 650 mg and acetaminophen (Tylenol) 650 mg produce

pain relief comparable to that of the opioids codeine 32 mg orally and meperidine (Demerol) 50 mg orally. Most non-opioids (other than acetaminophen) are potent anti-inflammatory agents called **nonsteroidal anti-inflammatory drugs (NSAIDs)**.

Nonsteroidal Anti-Inflammatory Drugs. Aspirin and other NSAIDs are very effective for inflammatory-type pain, such as early rheumatoid arthritis, mild to moderate postoperative pain, dental pain, menstrual pain, migraines, and muscle pain. These agents inhibit the synthesis of prostaglandins, which are fatty-acid substances found throughout the body. The release of prostaglandins in inflamed tissues causes pain, edema, and inflammation. By inhibiting the synthesis of these prostaglandins, anti-inflammatory drugs decrease inflammation and pain. NSAIDs are particularly useful in the management of acute inflammation such as that which causes postoperative pain.

! NURSING SAFETY PRIORITY**Drug Alert**

Aspirin and other NSAIDs can cause GI disturbances and decrease platelet aggregation (clumping together), which can result in bleeding. Therefore observe the patient for gastric discomfort or vomiting and for bleeding or bruising. If any of these problems occur, teach the patient and family to stop taking these drugs and to report side effects to the health care provider immediately.

When taking a patient history, ask about the use of NSAIDs, keeping in mind that the patient may not recognize store brand names as over-the-counter (OTC) NSAIDs. For example, Walprofen is Wal-Mart's brand name for ibuprofen; Walprofen is Wal-Mart's brand name for naproxen. Orudis contains ketoprofen, and Aleve contains naproxen. Ask the patient or patient's family to provide the name of each drug (prescription or OTC) that the patient is taking, as well as the daily dosage. Some patients may unknowingly take several types of NSAIDs at the same time, putting them at a high risk for adverse drug effects (ADEs).

The side effects of individual NSAIDs differ. For example, ibuprofen (Motrin) and naproxen (Naprosyn) appear to cause fewer GI problems than ketoprofen (Orudis). By adding

a GI protective drug such as misoprostol (Cytotec), GI side effects may be reduced.

Because of the high incidence of GI bleeding caused by NSAID use, particularly in older adults, selective cyclooxygenase-2 (COX-2) inhibitors, such as celecoxib (Celebrex), are recommended for long-term use. The COX-2 inhibitors selectively block the COX-2 enzyme responsible for inflammation and the production of substances associated with pain (e.g., prostaglandins). However, all COX-2 inhibitors have recently been associated with increased cardiovascular disease and may have limited use or be unavailable in the future.

Most older NSAIDs like ibuprofen block both COX-1 and COX-2 enzymes. The COX-1 enzyme is responsible for the gastric and renal side effects associated with older NSAID use. Patients may also become hypernatremic and experience hypertension from the resulting fluid retention. The primary cause of acute renal failure is long-term use of NSAIDs. Teach the patient to inform his or her primary care provider if taking OTC NSAIDs. Providers typically request follow-up laboratory testing to monitor for early indications of adverse drug events.

Patients with dental pain, osteoarthritis, and early rheumatoid arthritis treated with COX-2 inhibitors often demonstrate effective analgesia without GI side effects. There is no difference in the COX-2 analgesic efficacy or in renal side effects, but the decreased risk for GI bleeding makes these drugs more beneficial.

Acetaminophen. Unlike the rest of the non-opioid analgesics, acetaminophen (Tylenol) has few anti-inflammatory properties. Health care providers commonly prescribe acetaminophen for pain or fever. It exerts its analgesic action by blocking peripheral pain receptors, thus increasing the threshold of these receptors to painful stimuli.

Acetaminophen has some advantages over aspirin in that it is available in a liquid form (which is the best way to take oral analgesics) and it can be taken on an empty stomach. It causes no adverse GI effects. Therefore it is preferred for any patient who has a history of peptic ulcer disease. Acetaminophen also has no effect on platelet aggregation as most of the other non-opioids do. This drug is preferred, then, for people in whom bleeding is likely, such as preoperative or postoperative patients.

Acetaminophen does have several serious side effects, however, especially hepatotoxicity (liver toxicity) and **nephrotoxicity** (renal toxicity) with long-term use. Reports of liver toxicity have been associated with higher doses of the drug (1000 mg) taken more frequently than every 4 hours for long-term use. Teach patients that current recommendations restrict the total daily amount of acetaminophen to no more than 4000 mg (4 g). For *long-term* use, teach patients that no more than 3600 mg daily should be taken. Less than 2400 mg daily should be used in older adults.

! NURSING SAFETY PRIORITY

Drug Alert

Teach patients to tell their health care provider about the amount of acetaminophen they take each day. Remind them to have liver and renal function laboratory tests done on a regular basis as prescribed to monitor for early indicators of adverse drug events.

Teach patients to be aware of the amount of acetaminophen in combination products such as hydrocodone (e.g., Vicodin) and propoxyphene (e.g., Darvocet). The acetaminophen in these products limits their use for chronic pain. In addition, propoxyphene has a very long half-life and therefore should not be used for older adults. Patients with a decreased metabolism (e.g., hypothyroidism) should also avoid the use of long-term Darvocet. The U.S. Food and Drug Administration recently warned health care providers and patients to avoid taking propoxyphene in any form because it can cause life-threatening cardiac dysrhythmias or myocardial infarction.

Opioid Analgesics. Opioid analgesics are the mainstay in the management of all types of moderate to severe pain (see Table 5-4). They work centrally by blocking the release of neurotransmitters in the brain and/or spinal cord. Opioids are classified as full or mu agonists (morphine-like), partial agonists, or mixed agonists/antagonists. There are no advantages to the partial or mixed agonists, and they could precipitate a withdrawal if given to someone taking a full agonist.

The opioid **full agonists** bind to opioid pain (e.g., mu) receptors in the brain and block the release of substance P, decreasing pain sensation (Lilley et al., 2011). Agonists are the most potent of all analgesics.

Most opioid agonists are similar in pharmacologic effects, so a patient does not need more than one. Response varies widely from one person to another. Most opioids can be administered in many different routes—oral, transdermal, and IV. IM administration is seldom used because of uneven drug absorption and tissue pain and bruising. For patients on very large doses of opioids in end-of-life care, “opioid rotation” is another choice when ineffective analgesia or intolerable side effects occur.

There is no ceiling in the dose of a pure opioid agonist. The use of an equianalgesic chart when changing opioids is necessary, though, because these drugs vary in their oral to parenteral dosage strengths. The term **equianalgesic** refers to the dose and route of administration of one drug that produces about the same degree of analgesia as the given dose and route of another drug. This chart is useful to the health care provider when switching opioids or routes of administration of opioids.

Most commonly, 10 mg of morphine is the standard dose against which other opioids are measured. Equianalgesic opioid drug guides provide only the comparative analgesic potencies among these drugs. Dose modifications may be necessary according to each patient’s response.

CONSIDERATIONS FOR OLDER ADULTS

For older adults, the guideline is to “start low and go slow” with drug dosing, initially using no more than half of the recommended dose. Evaluate the patient’s response including whether the analgesic is effective in relieving pain. Although older adults may not be as sensitive as younger adults to mild pain, they feel moderate and severe pain as much as adults of any age (Baumann, 2009).

Examples of Opioid Drugs. A number of opioids can be used for pain control. Some are not as strong as others in their ability to control pain and are therefore not used as commonly. For instance, **codeine** is a short-acting weak drug that is the only opioid with a ceiling effect. It is considered a prodrug and is converted to morphine after ingestion. An

enzyme is necessary to convert a small amount of the codeine to morphine to be effective. An estimated 5% to 10% of people lack this enzyme, which could account for codeine's ineffectiveness in certain patients. For these patients, the conversion of codeine is so slow the drug is excreted before pain is relieved. This drug also has limited value for severe pain and should not be used in older adults because of the possible accumulation of a toxic metabolite, as well as constipation. For these reasons, it is more commonly used as an antitussive in a number of cough preparations unless the drug is combined with acetaminophen or other preparation.

Hydrocodone is similar to codeine and is available as a combination product with acetaminophen (Lortab, Vicodin) and ibuprofen (Vicoprofen). Because of this, the dose cannot be escalated because of the toxicities from the non-opioids. Therefore hydrocodone drugs have limited usefulness.

Other opioids are available when weaker drugs are not appropriate for the level of pain or if they are ineffective in controlling pain. Oxycodone is recommended for both acute and chronic pain. It is available as a single-agent, both in short-acting preparations (immediate-release) (OxyIR, Norvo [high-strength oral oxycodone]) and long-acting forms (OxyContin, Supeudol ♣). Any drug that ends in "Contin" is long-acting and therefore acts continuously. Oxycodone is also available in combination with aspirin (Percodan), or acetaminophen (Percocet, Tylox, Roxicet, Oxycocet ♣). Percodan is no longer on the market in Canada, but Oxycocet is available.

! NURSING SAFETY PRIORITY

Drug Alert

Give the long-acting form, *OxyContin*, every 12 hours and never crush or break the capsule. Teach the patient to swallow the drug whole rather than chew it, to allow the "time release" function of the drug. Liquid and rectal suppository forms of oxycodone are available for patients who cannot swallow the capsules.

Morphine (Roxanol, Avinza, Kadian ♣) is the gold standard opioid for both acute and chronic pain. It is available in many dosage strengths (both short- and long-acting) and can be given in virtually any route, including rectally. The immediate-release form is known as *MSIR*. MS Contin, Kadian, and Statex ♣ are examples of long-acting or slow-release forms of the drug. Liquid forms of these drugs are available for patients who cannot swallow the extended-release capsules. Morphine may also be administered by the subcutaneous, IV (diluted continuous or intermittent as needed), epidural, intrathecal, rectal, and IM (least preferred) routes. An intranasal form is also available, but the drug is poorly absorbed using this route.

Hydromorphone (Dilaudid, PMS-Hydromorphone ♣) is eight times more potent than morphine. It is available in both short-acting and long-acting forms (Palladone, Hydromorph Contin). Like morphine, hydromorphone is useful for all types of moderate to severe acute pain and chronic pain. Hydromorphone is being used more frequently for patients on IV patient-controlled analgesia (PCA) pumps or administered slowly as an IV push drug every 3 hours as needed for acute pain. The drug can also be given rectally in suppository form, intranasally, subcutaneously, or IM (least preferred).

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

A client has an order for hydromorphone (Dilaudid) IV push 1 mg every 3 hours. The drug is available as 4 mg/mL. The nurse administers _____ mL of hydromorphone for one dose.

Fentanyl (Sublimaze) may be used for chronic and acute pain. It is a potent opioid available in several forms for *chronic* pain:

- 72-Hour transdermal patch (Duragesic)
- Oral transmucosal lozenge (Actiq)
- Effervescent buccal oralets (Fentora)
- Intranasal spray (Instanyl)

Duragesic is used on a continuous basis to maintain pain control, especially in terminal cancer patients. Actiq lozenges and Fentora tablets are indicated for breakthrough cancer pain and should not be given to opioid-naïve patients (i.e., those who are not on opioids) (D'Arcy, 2007b). Breakthrough pain occurs primarily in patients with severe terminal cancer pain. The patient with breakthrough pain experiences pain between scheduled doses of the drug regimen. Other drugs may also be used for this purpose, but lozenges and buccal tablets are less invasive. Actiq is being used also for procedural-type pain.

For *acute* pain, fentanyl can be administered either IV push, with a PCA pump, or as an iontophoretic transdermal system (IONSYS). IONSYS is a needle-free, patient-activated transdermal system that forces medication deep into the skin using a weak electrical current powered by a battery-operated device. The most common use for this system is for patients with acute postoperative pain.

Methadone (Dolophine, Methadose) is the only full opioid agonist with a dual mechanism of action. It works on both the mu receptors and the N-methyl-D-aspartate (NMDA) receptors and is available in tablet, liquid, or subcutaneous form. Methadone is inexpensive and very effective for chronic pain but very complex and potentially unsafe to use. Practitioners need to be educated on the many drug/drug interactions, potential cardiac toxicity, and long half-life (24 to 36 hours). The FDA has recently come out with a black box warning because of several fatal overdoses. Analgesia lasts only 4 hours, but because of the long half-life, sedation and respiratory depression can occur more frequently than with other opioids. Patients must be monitored for sedation (especially days 2 to 3), and the drug should be used cautiously in older adults. When managing pain in a patient in a methadone maintenance program for substance abuse, be sure to increase the methadone dose for pain relief or add a second opioid.

Meperidine (Demerol) used to be routinely prescribed in acute care settings. Most health care agencies now have policies in place restricting its use to no more than 600 mg in 24 hours for no more than 2 consecutive days (Dobbins, 2010). Most agencies have discontinued its use altogether for older adults because of the resulting toxicities. Because of the accumulation and renal excretion of the toxic metabolite *normeperidine*, central nervous system toxicities may occur. Repeated doses of meperidine, particularly in older adults or in people with decreased renal clearance, may cause tremors, nervousness, delirium (acute confusion), seizures, and psychoses. Do not give meperidine in any form to older adults.

Oral and continuous infusions of the drug should not be administered to any patient.

The drug also blocks the reuptake of both serotonin and norepinephrine by the neurons and can cause serotonin syndrome. This potentially fatal condition is seen in patients taking meperidine with selective serotonin reuptake inhibitors (SSRIs), tricyclic antidepressants, triptan migraine drugs, or monoamine oxidase inhibitors (MAOIs). The early manifestations of this combination are central nervous system abnormalities like muscle rigidity and delirium, but the condition can progress to life-threatening cardiac dysrhythmias, hyperthermia, and disseminated intravascular coagulation (DIC).

Side Effects of Opioids. The most important type of opioid receptor is the mu receptor. **Mu opioids** cause side and adverse effects that include constipation, nausea and vomiting, urinary retention, pruritus (itching), sedation, and respiratory depression. These effects may be mistakenly viewed as allergies, but it is rare to be allergic to morphine-type drugs. The side effects (other than constipation in older adults) are time limited and easily managed (Table 5-5).

Nausea and vomiting may occur initially as a side effect in patients taking opioids for pain relief. Treating the nausea and vomiting with an appropriate antiemetic usually helps. In addition, if the patient needs to continue the opioid therapy longer than 1 week, the problem usually resolves on its own.

Opioids inhibit peristalsis in the GI tract. Patients who take regular doses of opioids almost always become *constipated*. Also, many patients in pain lack proper exercise and have an inadequate diet, both making the problem of constipation worse. Although constipation may seem like a minor side effect, it is not to the patient, especially the older adult. Often the discomfort of constipation is more distressing to the older adult than the pain itself.

Whenever a patient is started on regular doses of opioids at home, teach him or her how to prevent constipation (see Table 5-5). If the patient is unable to provide self-care, provide these interventions in the inpatient facility.

Because opioids have a depressant effect on the central nervous system, some drowsiness can be anticipated. However, *severe sedation* is not always caused by opioids. If the patient is still in pain, other causes of sedation should be ruled out before decreasing the opioid dosage or changing drugs. For example, drugs such as hypnotics or tranquilizers (diazepam [Valium], alprazolam [Xanax], or promethazine [Phenergan]) can cause sedation. Often the elimination of other central nervous system–depressant medications resolves the sedation problem.

! NURSING SAFETY PRIORITY

Critical Rescue

The key to assessing sedation is determining how easily the patient is aroused. *Stop the medication if the patient is difficult to arouse!* Assess each person's response to the first dose of an opioid. Be sure to assess the patient's level of consciousness. Monitor respiratory rate and depth, especially while sleeping.

Sedation occurs before opioid-induced respiratory depression, so nurse-monitored sedation levels are recommended by use of a sedation scale for opioid-naïve (not currently on an opioid) patients or those receiving opioids IV or epidurally. An example of a sedation scale is shown in Table 5-6.

TABLE 5-5 NURSING INTERVENTIONS TO PREVENT SIDE EFFECTS OF OPIOIDS

Constipation

- Assess previous bowel habits.
- Use measures to *prevent* this problem because constipation is the most common side effect (push fluids, encourage activity, give foods high in bulk and roughage).
- Keep a record of bowel movements.
- Administer stool softeners and stimulant laxatives.
- If ineffective, try suppository or Fleet's enema.

Nausea and Vomiting (N/V)

- Assess actual cause of nausea.
- Recognize that N/V may be only an initial, temporary side effect for the first 24 to 48 hours because tolerance seems to develop quickly to this side effect.
- Try an antiemetic prophylactically before administration as prescribed.
- Treat with antiemetic drug as prescribed.
- Give metoclopramide (Reglan) 10 mg before meals and at bedtime, or ondansetron (Zofran) 4 mg IV.

Sedation and Confusion

- Assess actual cause of sedation because the patient may also be on hypnotics and anxiolytic agents; eliminate unnecessary sedating medications.
- Recall that tolerance to this side effect generally occurs after 2 to 3 days.
- Be aware that stimulants such as caffeine may counteract opioid-induced sedation.
- Consider opioid rotation using an equianalgesic chart.

Respiratory Depression

- Be aware that clinically significant respiratory depression is rarely seen in patients with severe pain caused by cancer, even when large doses of opioids are given.
- Recognize that pain and stress seem to counteract the respiratory depression effects of opioids.
- Recall that respiratory depression occurs before sedation and possible lethal overdose.
- Monitor sedation level and respiratory status frequently for the first 24 to 48 hours, especially in opioid-naïve patients.
- If increased sedation occurs, decrease opioid dose and attempt to stimulate patient.
- Be aware that respiratory rate alone is not indicative of respiratory status.
- If absolutely necessary in an unresponsive patient, administer naloxone (Narcan) 0.4 mg diluted in 10 mL of normal saline; push 0.5 mL IV slowly for 2 minutes and observe the patient.

TABLE 5-6 EXAMPLE OF A SEDATION SCALE*

SCORE	MEANING
1	Awake and alert
2	Slightly drowsy, but easy to arouse
3	Always drowsy, but arousable
4	Somnolent, little or no response to stimuli

*For scores of 3 or 4, stop the medication and notify the health care provider.

A main reason for inadequate pain control is the exaggerated fear of respiratory depression. However, this problem rarely occurs, especially in patients taking opioids for chronic, long-term pain.

Patients develop tolerance to respiratory depression at the same time that they become tolerant to the analgesic effect of

an opioid. Pain appears to be nature's antidote to the respiratory depressant effects of opioids.

Opioid-induced respiratory depression can be treated. Respiratory depression is generally more likely to occur in an opioid-naïve patient than in an opioid-tolerant (currently on an opioid) one. It most often occurs at the onset and peak effect of the opioid. Naloxone (Narcan) and naltrexone HCl (Revia) are fast-acting IV opioid antagonists given to reverse the opioid effect and treat respiratory depression. These drugs should be administered only when absolutely necessary because they cancel the pain relieving effects of the opioid and can lead to withdrawal symptoms.

! NURSING SAFETY PRIORITY

Drug Alert

When giving opioid antagonists, administer them slowly until respirations increase to eight or more per minute. Continue to monitor the patient after giving these drugs because respiratory depression can recur. An opioid overdose can occur if the respiratory depression is not treated. Patients who are overdosed have only a few respirations each minute and constricted pupils. In some cases, respiratory arrest occurs.

Common Parenteral Routes of Opioid Administration. Opioids can be administered by all medication routes. Table 5-7 lists the routes with advantages and disadvantages. Effective management of pain requires the knowledge that the oral route is always the preferred route for most types of pain. The IV route is the most efficient route because of its rapid titration. Opioids are often given as IV push drugs or by patient-controlled analgesia. The IM route is not preferred for pain management because of its ineffectiveness in controlling pain and varying patient responses.

Patient-Controlled Analgesia. Patient-controlled analgesia (PCA) is a common way to combat the problem of inadequate analgesia by allowing the patient to control the dosage of opioid received. This approach to pain control can improve pain relief and increase patient satisfaction. It can also decrease the amount of opioid consumption per day when compared with nurse-administered intermittent dosing methods.

Patients who have ready access to an analgesic are more likely to medicate themselves before the pain becomes severe, and thus they may require a reduced amount. Having such control over drug administration also reduces anxiety, which helps relieve pain.

PCA is achieved using a PCA infusion pump (Fig. 5-4). Both stationary pole pumps (for hospital use) and ambulatory pumps (for nursing home or home use) are available. The infusion pump delivers the desired amount of drug through an IV access for pain. Morphine, fentanyl, and hydromorphone are the most commonly used drugs for PCA. Standing or preprinted orders from the health care provider are commonly used for PCA administration.

Drug security to avoid overdosing is achieved through a locked syringe pump system or locked drug reservoir system. The device is programmed to deliver a certain amount of drug (**demand dose**) within a specific interval known as a **lockout interval**. The health care provider specifies the amount of the demand dose. Morphine doses are typically 1 mg/mL, hydromorphone 0.2 mg/mL, and fentanyl 10 mcg/mL. Doses vary according to the patient's degree of pain. The lockout interval is typically 5 to 15 minutes.

FIG. 5-4 An ambulatory patient-controlled analgesia (PCA) infusion pump.

To prevent drug errors, two nurses program the dosing parameters into the PCA delivery device. When the patient presses the button or pendant (on ambulatory pumps), the appropriate bolus or demand dose is delivered. No drug is administered if the patient attempts to access the drug before the programmed time interval between doses. With this technique, there is little chance that patients will overmedicate themselves. *It is also recommended that all pumps have warning labels with large print that read "Patient only to push button" to prevent other people or staff from administering the medication, unless otherwise designated.*

The PCA regimen may consist of a demand-dosing-only schedule or a continuous infusion or **basal rate** with demand dosing. With demand or self-administered dosing only, the patient relies solely on a push of the pendant or bolus feature to seek pain relief. Continuous infusion of the opioid in addition to demand dosing provides more consistent analgesia and allows the patient to sleep without fear of missing any pain medication. However, when a continuous infusion is added to the regimen, some patients may be at greater risk for opioid-induced side effects (e.g., nausea and vomiting, sedation, respiratory depression), especially if the hourly dose is too high.

! NURSING SAFETY PRIORITY

Action Alert

Teach patients how to use the PCA and to report side effects, such as dizziness, nausea and vomiting, and inability to void. As with all opioids, monitor the patient's vital signs, particularly respirations, and check sedation level at least every 2 hours or per agency protocol.

When a patient is cognitively impaired or unable to push the PCA button, another method of administration should be considered. PCA means **patient-controlled**, so having someone else push the button defeats the purpose (PCA by Proxy). More important, this practice can cause oversedation and possible serious safety issues. *Because of serious sentinel events related to PCA overdoses, PCA by Proxy is not recommended but may be used in special cases.* Clear

TABLE 5-7 ROUTES OF ANALGESIC ADMINISTRATION

Oral**Advantages**

- Preferred route of analgesic
- Allows greater mobility and convenience
- Drug levels peak in 1 to 2 hours
- Greater patient satisfaction
- If patient is NPO or has a nasogastric or gastrostomy tube, medications can still be given enterally in liquid form
- Cost efficient
- Relatively steady blood levels produced

Disadvantages

- Slow onset
- Long-acting opioids cannot be crushed, broken, or chewed
- Some patients are unable to swallow or are NPO
- Requires functional GI system

Rectal**Advantages**

- Good for patients who are NPO, nauseated, or at home
- Easy for patients or caregiver to administer, especially older adults
- Duration of action may be immediate or extended depending on drug action
- Any opioid can be compounded by a pharmacist for rectal route
- Clinical practice suggests oral and rectal doses of analgesics fairly equal

Disadvantages

- May be more expensive than oral route and difficult to obtain
- Contraindicated in neutropenic patients and those with diarrhea, colostomy, or hemorrhoids
- May be culturally unacceptable

Intramuscular**Advantages**

- Used for acute short-term pain

Disadvantages

- Rapid peak effect but short duration of action and rapid fall-off
- Problems with absorption lead to inconsistent blood levels
- Painful administration
- Not recommended for chronic long-term pain, especially cancer pain
- Patient depends on others to administer injection
- Not recommended for use with emaciated patients or patients with decreased muscle mass
- Long-term use can cause fibrosis and sterile abscesses

Transdermal**Advantages**

- Most common example is fentanyl (Duragesic) used for breakthrough pain
- May improve patient adherence to drug regimen
- Noninvasive, convenient, and well accepted by patients

Disadvantages

- Because of gradual increases in plasma concentration, may need to supplement with short-acting analgesics for first 12 to 24 hours after initial application
- Appropriate only for patients who are opioid-tolerant
- Difficult to adjust dose
- Febrile patients absorb medication quickly
- Less useful for patients with generalized edema

Transmucosal**Advantages**

- Good bioavailability, rapid peak effect
- FDA-approved for breakthrough cancer pain
- May be useful for procedural pain
- Faster for pain relief than oral forms

Disadvantages

- Sweetened matrix contains 2 g sugar, but still may taste bitter
- Short-acting, short half-life
- Must be swabbed inside mouth for at least 10 minutes to dissolve completely
- Not useful for cognitively impaired patients

Topical**Advantages**

- Easy to use
- Little systemic absorption
- Lidoderm patch, EMLA topical cream, and capsaicin cream are examples

Disadvantages

- May cause skin reactions
- Capsaicin causes burning initially

Sublingual**Advantages**

- Most opioids can be absorbed sublingually
- Good for patients with no IV access and/or impaired swallowing

Disadvantages

- May not be absorbed or may cause mucosal irritation

Intranasal**Advantages**

- Fentanyl is commonly given this way; sumatriptan for migraine headaches is also available in this form
- Convenient and easy to use
- Effective and fast pain relief
- Appropriate for ambulatory care use

Disadvantages

- Cannot be used by patients with cognitive impairment or by those who are extremely ill or in a coma

Subcutaneous**Advantages**

- Available as bolus, continuous infusion, or continuous infusion with patient-controlled analgesia (PCA)
- Avoids need for IV access and cheaper than IV
- Readily managed at home
- Recommended for cancer patients who cannot take anything by mouth and in whom IV access is not desirable
- Avoids repetitive injections and is less painful
- Continuous infusion
- Avoids peaks and valleys in bloodstream; maintains steady blood level
- Provides prolonged parenteral administration of opioid
- No delay in drug administration

Disadvantages

- Subcutaneous boluses have slower onset and a lower peak effect than IV boluses
- Requires use of ambulatory infusion pump, which is not always patient acceptable

Continued

TABLE 5-7 ROUTES OF ANALGESIC ADMINISTRATION—cont'd

Intravenous

- Available as bolus (IV push), continuous infusion, or PCA IV bolus on demand

Advantages

- Good for acute pain or procedures
- Immediate pain relief
- Provides fastest onset but shortest duration
- Peaks in 5 to 15 minutes
- Eliminates anxiety and prevents pain
- Recommended when unable to achieve pain control through oral or rectal routes with high dosages of opioid or unable to use oral/rectal route
- Continuous IV administration provides steady blood level

Disadvantages

- Not recommended for constant pain because of peaks and valleys in bloodstream
- Requires use of infusion pump with an alarm

Patient-Controlled Analgesia (PCA)**Advantages**

- Allows patient to receive a predetermined IV bolus of an opioid by hitting a syringe pump mechanism
- Gives patient sense of control, less anxiety
- Provides quick and consistent pain relief
- Maintains a constant level of pain relief

- Eliminates the need for repeated injections

- Saves time
- Especially recommended for acute pain such as postoperative pain

Disadvantages

- Requires use of a pump
- Requires reinforced patient teaching for maximum effectiveness
- Requires two nurses to program to prevent errors (in hospitals)
- Requires designated person to hit button if patient cannot

Spinal (Epidural and Intrathecal) Administration**Advantages**

- Opioid (usually morphine or fentanyl) administered through catheter into epidural or intrathecal space; ziconotide (Prialt) used intrathecally
- Preservative-free morphine or fentanyl used
- Useful for postoperative pain (abdominal, thoracic, orthopedic) or chronic pain
- May be intermittent bolus or by continuous infusion pump

Disadvantages

- Careful patient selection is necessary because procedure is expensive and may be risky
- Side effects include nausea, vomiting, pruritus, sedation, urinary retention, and respiratory depression
- Possible complication of hematoma and infection and/or meningitis

FDA, Food and Drug Administration.

guidelines and monitoring procedures must be in place for PCA use. In the event that a patient is unable to push the button, *one authorized agent*, such as a close family member, for controlled analgesia may be clearly designated.

**NCLEX EXAMINATION CHALLENGE****Physiological Integrity**

A nursing assistant reports that a client receiving PCA morphine is very drowsy and has a respiratory rate of 10 breaths/min. What is the nurse's best action at this time?

- Continue to monitor the client for further changes.
- Assess the client with a focus on sedation and respirations.
- Stop the PCA morphine infusion immediately.
- Call the physician to report the client's changes.

Epidural Analgesia. **Epidural analgesia** (also known as *peridural* or *extradural analgesia*) refers to the instillation of a pain-blocking agent, usually an opioid analgesic alone or in combination with a local anesthetic like bupivacaine, into the epidural space. Epidural analgesia is used for the management of acute pain, such as postoperative pain, and chronic cancer pain. It has been used since the 1950s but has become more popular as newer and more innovative approaches to acute pain control are explored. Epidural analgesia is used primarily in patients who are predisposed to respiratory complications, including those undergoing thoracic, orthopedic, and abdominal surgery, those with pre-existing respiratory disease, and those who are obese. In some states, the nurse practice act allows registered nurses to remove epidural catheters. All practitioners who care for patients with

epidural catheters must be properly educated. If given, low-molecular-weight heparin is withheld on the day the epidural is to be discontinued. This intervention reduces the chance of bleeding complications.

Morphine (preservative free), hydromorphone (Dilaudid), and fentanyl (Sublimaze) are the most commonly used opioids for epidural administration and are often given by a patient-controlled epidural analgesia (PCEA) pump. Sufentanil (Sufenta), a derivative of fentanyl but more potent, may also be used. A local anesthetic such as bupivacaine (Marcaine), which affects both sensory and motor nerves, may be given alone or in combination with an opioid. *Low* concentrations of local anesthetics are used to prevent significant sensory and motor deficits. Lower motor weakness is far less common with ropivacaine (Naropin) when compared with bupivacaine because it is more selective for sensory nerves.

Using a combination of opioids, non-opioids, and local anesthetics for postoperative pain (as just described) is sometimes referred to as **multimodal analgesia** or **balanced analgesia**. The advantage of these drug combinations is to provide better pain control at lower doses than any single drug does. Another advantage is that these drugs *decrease* the surgical stress response, which is typically mediated by multiple endocrine and metabolic changes. These changes contribute to increased pain, GI distress, confusion (especially in older adults), and cardiopulmonary complications. Balanced analgesia, then, not only decreases pain but also helps decrease other problems that result from the stress of surgery. It is especially appropriate for patients having complex surgeries, such as those undergoing abdominal or thoracic procedures.

A temporary, externalized epidural catheter is used for acute pain control. This device is not sutured to the skin and is easily dislodged. Be sure to tape the catheter in two places to anchor it properly. Some clinicians do not recommend transparent dressings because the catheter may be dislodged when the dressing is removed. The catheter is generally placed in either the lumbar or the thoracic region. Rarely is the catheter placed above the level of the sixth thoracic vertebra, because the diaphragmatic muscle may be affected by the analgesic.

Complications that occur with epidural analgesia are directly related to catheter placement, catheter maintenance, and type of analgesic. Infection, *although rare*, results from a failure to maintain aseptic technique during catheter placement, direct drug instillation, and infusion solution and tubing changes. Infection also results from a failure to maintain aseptic conditions for indwelling catheters at the site of insertion or at the site of tube junctions. To prevent infections, ensure that all catheter line connections are secure and that an occlusive sterile dressing is maintained over the site.

For some surgical patients, a single injection of a morphine sulfate extended-release drug (DepoDur, Duramorph, Epimorph) may be administered. Duramorph may also be given intrathecally or IV. This procedure does not require an indwelling epidural catheter and can be given before or after surgery. Most typically, this drug is used for patients having total joint replacements or abdominal surgery. The drug often lasts up to 48 hours, which reduces the patient's need for usual postoperative medications.

Pruritus (itching) and nausea and vomiting are common side effects of epidural opioids. Pruritus is first treated with a small amount of naloxone (Narcan). Because epidural-induced pruritus does not appear to be caused by histamine release, diphenhydramine (Benadryl, Allerdryl) may not be effective in relieving itching and may work only via its sedating effects. The health care provider usually prescribes an antiemetic as needed for nausea and vomiting.

Patients who receive epidural opioids are also at risk for respiratory depression resulting from high plasma or cerebrospinal fluid concentrations of the instilled drug. Those receiving epidural therapy with only a local anesthetic are not at risk for respiratory depression. Because of its potential for greater spread up the spinal cord, morphine is more likely than fentanyl to cause respiratory depression. Morphine is preferred to fentanyl when a larger distribution of analgesia is required (e.g., pain relief from extensive abdominal wounds).

Monitor the patient's respirations and sedation level at frequent intervals during and after the administration of epidural opioids, and immediately report any concerns to the health care provider (see Table 5-6). Opioid-induced respiratory depression usually occurs within the first few hours of administering fentanyl but may not be seen for 12 hours or more when morphine is given. This complication is managed by administering low doses (0.2 mg) of IV naloxone (Narcan).

Urinary retention is another common problem associated with epidural analgesia, but it occurs no more frequently than urinary retention after surgery in patients not receiving epidural analgesia. Although the cause is not clear, this problem usually occurs during the first or second day of analgesic administration and may be treated with bethanechol chloride (Urecholine) or intermittent urinary catheterization. The

incidence of this complication is less than 25% and is more likely to occur in men than in women.

! NURSING SAFETY PRIORITY

Action Alert

Lower motor weakness is common when an epidural local anesthetic is used in combination with the opioid. Assist patients who get out of bed for the first time to determine the degree of leg weakness. Do not delegate this activity and assessment to unlicensed assistive personnel!

Epidural analgesia may also be used for *long-term* chronic pain relief. Such pain is usually the result of cancer or central sensitization. A permanent epidural catheter may be inserted, and several catheter devices are available for this purpose. The DuPen Silastic catheter (Davol) is a commonly used **external catheter**. A portion of the catheter exits the skin. Drugs can be intermittently injected into this portion, or the catheter can be attached to an infusion device for continuous drug administration.

Implantable devices are also used to treat chronic pain. The epidural Port-A-Cath (SIMS Deltec, Inc.) is implanted under the skin, and the catheter portion is inserted into the epidural space. As with the DuPen catheter, this device can be injected with drugs intermittently or can be connected to an infusion device for continuous opioid delivery. Injectable ports are shown to reduce the incidence of catheter dislodgement and early infection. Systems consisting of either an externalized catheter or a drug delivery device are rarely used for intrathecal drug administration. The SynchroMed pump (Medtronic, Inc.) is a totally implantable system that contains a drug reservoir. The drug reservoir is filled on a routine basis and is capable of continuously administering a certain volume of drug each day (Fig. 5-5). However, this device must be used cautiously due to its potential for injecting too much medication into the patient.

The side effects of long-term epidural opioids are common in patients who have had little exposure to opioids. Those who receive this therapy are usually more tolerant of the effects of opioids and may not require the rigorous monitoring needed for postoperative analgesia. Male patients receiving long-term epidural opioids may have sexual dysfunction, decreased libido, and difficulty maintaining an erection; female patients may experience amenorrhea. Testosterone injections seem to help improve sexual function in males.

Intrathecal Analgesia. **Intrathecal (subarachnoid) analgesia**, in which a pain-blocking agent is introduced into the space between the arachnoid mater and pia mater of the spinal cord (where cerebrospinal fluid is located), may be considered for long-term management of **intractable pain** (chronic pain that cannot be managed using standard therapies).

Ziconotide (Prialt) is an effective non-opioid analgesic that is infused intrathecally using an implanted pump and catheter. Like many other drugs, it is best tolerated when started at a low dose and increased slowly no more than once a week. Ziconotide is most effective for neuropathic, nociceptive, and mixed pain (Mitchell et al., 2008). The most common adverse effects are dizziness, nausea, and confusion, which often disappear after a dose reduction. More severe, but far less common, effects include psychosis and neurologic impairment. About 40% of patients on the drug have elevated

FIG. 5-5 A SynchroMed implantable pump (**A**) and spinal catheters (**B**) for delivery of a precise volume of long-term intraspinal analgesic each day.

serum creatine kinase levels, but patients are usually not symptomatic. Teach patients and their families to closely monitor for neuromuscular symptoms, such as myalgias or muscle cramps (Mitchell et al., 2008). Tell them to inform the health care provider immediately if these manifestations occur.

Adjuvant Analgesics. Always consider the use of adjuvant analgesics, especially for patients with chronic pain or complex pain syndromes. Although not true analgesics, the **adjuvant drugs** relieve pain either alone or in combination with analgesics. These drugs can potentiate or enhance the effectiveness of the analgesic.

The use of adjuvant analgesics not only can provide additional pain relief in some cases but also can help control other discomforts associated with pain (anxiety, depression, nausea, insomnia). Table 5-4 gives examples of adjuvant medications.

Some **antiepileptic drugs** (AEDs or anticonvulsants), such as gabapentin (Neurontin) and pregabalin (Lyrica), are effective in treating postherpetic neuralgia, fibromyalgia (Lyrica), and the painful neuropathy associated with diabetes mellitus and cancer. They have been useful in many patients with neuropathic pain from back injuries as well. Doses of gabapentin can be escalated up to 3600 mg daily with few side effects compared with other anticonvulsants. Topiramate (Topamax) is another AED with promise for neuropathic pain, and it causes weight loss, rather than gain like most of the tricyclic antidepressants. Because most AEDs can cause hyponatremia, monitor electrolyte values carefully, especially in older adults.

The older **tricyclic antidepressants**, such as amitriptyline (Elavil), nortriptyline (Pamelor), and imipramine (Tofranil), have been beneficial in treating chronic neuropathic pain. However, the newer **serotonin-norepinephrine reuptake inhibitors** (SNRIs), such as duloxetine (Cymbalta) and venlafaxine (Effexor), are more often used, especially for older adults. Severe adverse drug events are associated with the

longer-acting tricyclic drugs (e.g., constipation, urinary retention, confusion). The tricyclics are also contraindicated in people with a history of seizures or cardiac disease.

In some cases, **antianxiety agents** help relax the patient and thus help relieve pain. However, many of these drugs cause confusion, drowsiness, and hypotension; the health care provider selects the drugs with the fewest side effects. Examples of antianxiety agents are alprazolam (Xanax), lorazepam (Ativan), and oxazepam (Serax, Zapex). Clonazepam (Klonopin), also used for anxiety, has been shown to be particularly helpful for certain types of nerve injury pain.

Although used for centuries in China and other eastern countries, **cannabinoids** are just now gaining a role in pain management in the United States. Several states allow medical marijuana for pain management under the supervision of a licensed primary care provider. Oral extract and smoked forms of the drug are available, but the few existing studies have only examined the effectiveness of oral forms. For patients taking these drugs, observe for sedation, ataxia, vertigo, and disorientation. A 5-mg to 10-mg dose is usually recommended. Cannabinoids are used most often for patients with chronic pain, but studies have demonstrated their effectiveness in relieving acute pain (Gevirtz, 2009).

Oral local anesthetics, such as mexiletine (Mexitil), act by suppressing the electrical activity of both peripheral nerves and neurons in the central nervous system. They are useful for electric shock-like pain and continuous pain. Mexiletine is contraindicated for patients who have cardiac conduction defects or dysrhythmias or are currently taking cardiac anti-dysrhythmia drugs.

A more recent technique used for adjuvant postoperative pain management is **local anesthesia infusion pumps**. Several brands are on the market: ON-Q PainBuster® (see Fig. 15-13 in Chapter 15) and I-Flow®. These pumps are filled with a local anesthetic, such as bupivacaine, and slowly release the drug over several days. They are inserted by the surgeon and used mainly for spinal fusions, total hip repair, and other

orthopedic surgeries. Most patients are taught to remove the pump themselves when they return home. Health professionals need to be aware that some of these pumps may contain latex, so people with allergies must be made aware. The principle of combination treatment is very useful with these pumps because patients use less systemic drugs and therefore experience fewer side effects.

Topical drugs can be useful, particularly for localized neuropathic pain, and have no major systemic effects. For example, the *lidocaine patch* (Lidoderm) is approved for postherpetic neuralgia. Up to three patches can be applied at once, or they can be fitted to the painful area. The patch should be put on for 12 hours and removed for 12 hours. There is virtually no systemic absorption of lidocaine.

The *diclofenac patch* (Flector) is a fairly new NSAID drug for topical pain control. It is used to help manage mild musculoskeletal pain (e.g., sprains, strains) and is a safer option than oral NSAIDs. It should not be used if the patient is taking other NSAIDs. Long-term use of the patch can cause similar side effects to those caused by the oral form.

EMLA and *ELA-Max* creams are combinations of topical lidocaine and prilocaine. These must be applied to intact skin at least 45 minutes before needle sticks. The topical medications for pain relief have rare side effects, including local skin reactions.

Local short-acting gels and creams may provide *cryotherapy* to decrease pain, especially for muscle aches and pains. These products can often be bought over-the-counter (OTC) (e.g., BENGAY, Icy Hot). The effects of this type of application last about 1 to 2 hours, depending on the patient.

DECISION-MAKING CHALLENGE

Patient-Centered Care; Evidence-Based Practice

A middle-aged nurse educator was recently diagnosed with four bulging disks in her neck. She has had severe neuropathic pain for several months and has self-medicated with high doses of ibuprofen and acetaminophen. The adult nurse practitioner also started her on Tylenol #3 one tablet every 4 hours as needed for pain. The patient does not want to have surgery unless she develops spinal cord compression. As her office nurse, you are providing health teaching.

1. What questions will you ask the patient at this time in preparation for teaching?
2. How might you find the best evidence to help prepare her teaching plan?
3. What adjuvant drugs might this patient take to help her with her type of pain?
4. In view of her profession, what nonpharmacologic methods might benefit her? How will you determine if they are appropriate for her values and beliefs?

Nonpharmacologic Interventions

A number of effective interventions for pain are nonpharmacologic. These may be used alone for mild to moderate pain or in combination with drug therapy for more severe pain. Nonpharmacologic therapies are classified as either physical measures or cognitive-behavioral measures. Some may be referred to as part of complementary and alternative medicine (CAM), such as imagery, therapeutic touch, and hypnosis. CAM is not considered part of conventional medicine. Many patients pay a great deal of money out of pocket because these techniques are not commonly covered by insurance. These therapies often enhance, not

replace, drugs for pain management. Chapter 2 discusses CAM in more detail.

Physical Measures. Physical measures may be used instead of or in addition to drug therapy to relieve pain. Most of these measures are categorized in the literature as complementary and alternative therapies. *Cutaneous (skin) stimulation* strategies to relieve pain have been in use for many years. Various types of stimulation to the skin and subcutaneous tissue produce pain relief. Nurses play an important role in educating patients about these techniques. Methods of cutaneous stimulation include these techniques:

- Application of heat, cold, and pressure
- Therapeutic touch
- Massage
- Vibration

Whichever method is used, several issues must be considered:

- The benefits of these techniques are highly unpredictable and may vary from application to application.
- Pain relief is generally sustained only as long as the stimulation continues.
- Multiple trials may be necessary to establish the desired effects.
- Stimulation itself may aggravate pre-existing pain or may produce new pain.

Despite the drawbacks to cutaneous stimulation, it can be effective in the management of both acute pain and chronic pain. These techniques have both physiologic and psychological effects on the patient. Cutaneous stimulation techniques also give patients an opportunity to participate actively in the management of their pain.

Collaborate with the physical or occupational therapist for patients having pain to increase function, decrease pain, compensate for decreased function, and prevent further deterioration. Exercises and physical modalities such as heat, cold, or massage may be used. Expected patient outcomes include an increase in the range of motion, strength, and function of the affected area, and an improved quality of life.

The occupational therapist may also help decrease pain by making one or more splints to rest severely inflamed joints. These devices are most often used short-term and intermittently for patients with osteoarthritis or rheumatoid arthritis.

Transcutaneous electrical nerve stimulation (TENS) may be used as an adjunctive treatment for pain (Baumann, 2009). For older adults, it may be safer and just as effective as drug therapy. Although there are several types of TENS units, each involves the use of a battery-operated device capable of delivering small electrical currents through up to four electrodes applied to the painful area (Fig. 5-6). The voltage or current is regulated by adjusting a dial to the point at which the patient perceives a prickly “pins-and-needles” sensation. The current is adjusted based on the degree of pain relief and level of comfort.

Other cutaneous techniques, such as touch, pressure, massage, vibration, and heat and cold application, stimulate the skin and somehow interrupt the pain pathway. These interventions are relatively easy to learn and are fairly economical. Cold applications are especially helpful for inflamed areas. Heat is appropriate when an increased blood flow is desired, such as for patients with chronic arthritis. Paraffin dips for the hands are particularly helpful for those patients

FIG. 5-6 Application of a transcutaneous electrical nerve stimulation (TENS) unit.

to increase movement. Warm showers and compresses that can be done at home are also useful in reducing stiffness and promoting movement in patients with arthritis, especially after awakening.

Cognitive-Behavioral Pain Management. Cognitive-behavioral pain management (CBPM) has been popular for years, mainly as an adjunct to drug therapy. Theoretical explanations for the effectiveness of these measures reflect the premises of the gate control theory. Examples of CBPM strategies are distraction, imagery, relaxation, and hypnosis. (See [Chapter 2](#) for further discussion of cognitive-behavioral complementary therapies.)

Distraction can be an effective method of acute pain relief. Simple measures such as holding a patient's hand, taking him or her for a walk, or encouraging deep-breathing exercises can divert attention from the pain. Nurses often observe that patients request less pain medication when family members are present and when talking on the phone. After visiting hours, many patients request something for pain because they are no longer distracted.

Distraction alters the perception of pain but does not influence the cause or peripheral mechanism of pain. Visual distractors (e.g., pictures, television) can divert the attention to something pleasant or interesting. Auditory distractors, including music or relaxation tapes, can have a calming effect. Changing the environment can remove unpleasant stressors or reminders that may enhance pain. Physical distractions (e.g., deep-breathing exercises) help the patient concentrate on other physiologic sensations. Respect the patient's preferences and values when suggesting these management modalities.

Distraction can be particularly useful in these situations:

- Exacerbations of pain
- Painful procedures (e.g., dressing changes, invasive procedures)
- Interrupting the patient's constant perception of pain

Imagery is a form of distraction in which the patient is encouraged to visualize or think about some pleasant or desirable feeling, sensation, or event. Guided imagery occurs when a person, often a nurse, assists the patient in sustaining a sequence of thoughts aimed at diverting attention away from the pain. Intense concentration is required to visualize images. Those who are extremely anxious, agitated, or unable to concentrate may first benefit from mild distraction.

Imagery is particularly useful for chronic pain; however, it works for some patients but not for others. Patients who practice this technique can mentally and vividly experience sights, sounds, smells, events, or other sensations. The nurse first assesses the patient's level of concentration to determine whether he or she can sustain a particular thought or thoughts for a desired time. The time interval for mental imagery can vary from 5 to 60 minutes. Behaviors that are helpful in assessing the capacity for imagery include:

- Reading and comprehending the newspaper
- Listening to music or other auditory stimuli
- Having the ability to follow and participate in sustained conversation
- Having an interest in environmental surroundings

When the patient has demonstrated some ability to concentrate, assist him or her in identifying a pleasant or favorable thought. Encourage the patient to focus on this thought to divert attention away from painful stimuli. Audiotapes or CDs may help form and maintain images. The nurse, patient, or family may wish to create these, or commercially available tapes and CDs may be used. This is an example of guided imagery instructions:

Imagine being on the beach of a deserted island. You can hear the sound of waves rushing onto the shore, the cry of seagulls flying high above, and the rustling of trees as they are brushed gently by the wind. You can feel the warmth of the sun over your body and the cooling breeze.

Patients may also use *relaxation techniques* to reduce anxiety, tension, and emotional stress, all of which may exacerbate pain. Techniques to promote relaxation can be both physical and psychological. Physical relaxation techniques include:

- Receiving a body massage, back rub, or warm or hot bath
- Modifying the environment to reduce distractions
- Moving into a comfortable position

Psychological relaxation techniques include:

- Pleasant conversation
- Music
- Relaxation tapes

Some relaxation tapes assist the patient with progressive relaxation of the muscles. Relaxation exercises can be effectively coupled with guided imagery, distraction, and hypnosis.

Hypnosis is an altered state of consciousness in which a person enters a trance and loses an overall sense of reality. Although the person is in a trance, he or she has some sense of awareness and contact with reality and has an understanding of what is actually happening. Hypnosis can be used to treat a variety of pain syndromes, particularly chronic pain. It is used to help patients overcome the emotional consequences of pain and can promote a positive state of mind. Although nurses do not usually teach hypnosis, they are in a key position to help clarify misconceptions, instruct patients

about relaxation and distraction, and encourage them to practice self-hypnosis.

Other Complementary and Alternative Therapies. The data are controversial regarding the usefulness of other pain management techniques, such as magnet therapy and herbal supplements like glucosamine for osteoarthritis. Although not supported by research, some patients believe that magnets applied to the skin or worn in shoes can reduce pain. This is a noninvasive therapy, and there is no harm to those who use this modality.

The ancient Chinese practice of *acupuncture* is becoming more popular in Western countries for the treatment of pain and for anesthetic purposes during diagnostic procedures, labor and delivery, and surgery. It is also used to help patients change certain behaviors (e.g., smoking cessation). [Chapter 2](#) describes this complementary therapy in more detail.

Invasive Techniques for Chronic Pain

Invasive techniques are used to interrupt the pain pathways when pain is intractable (not able to be relieved) or severely debilitating. Depending on the technique, some degree of neurologic deficit and nerve destruction is expected. Various invasive techniques are used when chronic or persistent pain can no longer be adequately controlled with drugs or other pain-reducing methods. Examples include temporary or permanent *nerve blocks* with local anesthetics or other agents. *Because of high failure rates and serious neurologic complications, these procedures are rarely used.*

Spinal cord stimulation offers a more invasive method of nerve stimulation and is becoming more popular as a method of chronic pain control when other methods fail. This technique involves the use of electrodes implanted under the skin and into the area of the nerve responsible for the pain. At first, a trial of spinal cord stimulation is attempted using temporary externalized electrodes that are implanted and connected to a stimulator device. The amount of electrical current is adjusted to provide pain relief without additional discomfort. If this trial is successful, the patient undergoes surgery for placement of a permanent implantable stimulator.

NURSING SAFETY PRIORITY

Critical Rescue

After surgery, be sure to perform frequent neurologic assessments, especially on the lower extremities. If the patient reports any changes in movement ability or sensation, report these findings to the surgeon immediately and document carefully. Hematoma formation or other complications can lead to paralysis.

Community-Based Care

The pain experience extends beyond hospitalization. Many patients have chronic pain but are not hospitalized. Others are in nursing homes or assisted-living facilities and have chronic pain, often not well managed. If the patient is hospitalized, coordinate continuing pain management strategies before discharge. Ensure that the patient, especially one who is on opioids, has a prescription for pain medication to last at least until the first follow-up visit.

Home Care Management

Together with the patient and family, the nurse, case manager, discharge planner, or occupational therapist determines

whether modifications are necessary for maintaining a reasonably pain-free regimen after discharge. Fatigue heightens the awareness of pain. If physical modifications (e.g., installing a downstairs bathroom) are unrealistic, suggest schedule changes, role responsibilities, and daily routines to help avoid fatigue.

At home, patients may require a referral for physical therapy, especially to start or continue treatment with cutaneous stimulation or heat or cold techniques. Patients may need a clinical nurse specialist in pain management or a social worker to assist them in developing coping strategies or maintaining adequate family dynamics. A hospice referral (hospital- or community-based) can help maintain continuity of care in the management of terminally ill patients. Those with cancer may be at risk for developing uncontrolled pain that results in hospitalization if it cannot be managed at home.

Home infusion therapy programs provide a wide variety of services to patients who require technology-supported pain care at home. Many of these services depend on approval by the insurance carrier, usually before analgesic options are considered and therapy is started. Well-defined home agency practices and professional support at home are required if patients leave the hospital with infusion therapy for pain management.

Teaching for Self-Management

Teach the patient and family about analgesic regimens, including any technical skills needed to administer or deliver the analgesic, the purpose and action of various drugs, their side effects or adverse reactions, and the importance of dosage intervals. Explain how to prevent or treat the constipation commonly associated with taking opioid analgesics and other pain medications.

In addition, explain that, ideally, the analgesic regimen should not interfere with the patient's sleep, rest, appetite, level of physical mobility, or driving ability. If this problem occurs, encourage the family or other caregiver to consult with the health care provider or home care nurse, as appropriate.

In patients with pain from advanced cancer, all efforts are directed toward maximizing pain relief and symptom control at home to eliminate unnecessary re-admissions. This may mean that the health care provider prescribes a flexible analgesic schedule that allows the patient to adjust analgesics according to the amount of pain. Teach the patient and family how to safely increase the drug within the prescribed dosing guidelines.

Evaluate family support systems to assist the patient in adhering to and continuing the proposed medical treatment and nursing plans. Inform and include family members in activities during and after hospitalization.

To achieve a reasonable level of expectation for the patient, suggest ways to continue participation in household, social, sexual, and work-oriented activities after discharge. Help identify important activities, and plan them around adequate rest schedules.

The patient with chronic pain needs continued support to cope with the anxiety, fear, and powerlessness that often accompany this pain. Help the patient and family or significant others identify coping strategies that have worked in the past. Outside support systems are also identified, such as self-help organizations.

Health Care Resources

Refer the patient to home health when you anticipate that he or she will require assistance or supervision with the pain relief regimen at home. This referral should include specific information about the patient's overall physical condition, general level of sedation, weakness or fatigue, possible constipation or nutritional problem, sleep patterns, and functional status. Use a structured procedure such as SBAR to communicate this information.

In addition to explaining the patient's physical status to the home care nurse, describe the patient's level of anxiety and general expectations about pain status after discharge. Close relationships and available support network are

important factors in providing ongoing support for effective pain intervention strategies.

Referral to an advanced practice nurse pain specialist, social worker, or psychologist is an appropriate way to continue providing support to the patient and family, reinforce instructions for cognitive-behavioral strategies to deal with pain, and evaluate overall physical and emotional adaptation after discharge. When severe chronic or intractable pain exists, health care professionals should direct the patient and family to appropriate resources such as pain centers or health care providers who specialize in long-term pain management.

GET READY FOR THE NCLEX® EXAMINATION!

KEY POINTS

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- The nurse is legally and ethically responsible for acting as an advocate for patients experiencing pain.
- Coordinate the patient's plan of care as he or she transfers between health care agencies; be sure that the plan of care is communicated clearly.

Health Promotion and Maintenance

- Provide information to the patient and family about complementary and alternative therapies as needed; these modalities are additions to, not replacements for, the established plan of care.
- Consider the special needs of older adults when assessing and managing their pain (see [Chart 5-1](#)).

Psychosocial Integrity

- Be aware that some nurses and physicians have biases about pain assessment and management; be objective when caring for any patient in pain.
- Provide information to patients who have misperceptions about pain and pain management.

Physiological Integrity

- Pain is what the patient says it is; self-report is always the most reliable indication of pain.
- Perform a complete pain assessment, including duration, location, intensity, and quality of pain.
- Three major types of pain have been identified—acute, chronic cancer, and chronic non-cancer.
- Acute pain serves as a warning to the body, causing sympathetic responses such as increased heart rate, increased blood pressure and pulse, dilated pupils, and sweating.
- Both types of chronic pain do not cause sympathetic reactions; therefore some patients do not appear to be in pain, even when they are.

- The gate control theory has helped explain the mechanism of pain and its management.
- Factors that affect pain and its management include age, gender, genetics, and culture.
- Tolerance implies that the patient has adapted to a drug and that, over time, its effects decline; physical dependence is manifested by a withdrawal reaction; addiction is a primary, chronic disease that occurs over a long period. Behaviors in addiction include craving, compulsive drug use, and continued use despite harm.
- Never use placebos for any patient; their use in non-research-based practice is unethical.
- Non-opioid drugs are the first-line therapy for mild to moderate pain; NSAIDs and acetaminophen (Tylenol) are commonly used drugs in this category.
- NSAIDs should be used with caution in older adults because of adverse effects, such as GI disturbances, bleeding, and sodium and water retention.
- Acetaminophen can cause hepatotoxicity and nephrotoxicity with long-term use.
- The opioid full agonists are most effective for both acute and chronic pain management; they bind to mu receptors and block pain transmission.
- Equianalgesic charts are useful when changing from one opioid to another; morphine 10 mg is the standard dose against which other opioids are measured.
- Morphine and *similar mu agonists* are the gold standard drugs for both acute and chronic pain and are available in many forms, both short acting and long acting.
- Other commonly used mu agonists include oxycodone, hydromorphone, and fentanyl.
- Meperidine is an outdated drug and is rarely used. Its toxic metabolite (normeperidine) can accumulate, especially in the older adult or someone with decreased renal clearance, and can cause seizures and confusion.
- Observe for and prevent common side effects of opioids including nausea and vomiting, constipation, sedation, and respiratory depression (see [Table 5-5](#)).

GET READY FOR THE NCLEX® EXAMINATION! —cont'd

- Table 5-7 summarizes the advantages and disadvantages of drug therapy by route of administration.
- Multimodal (balanced) analgesia for epidural pain management is a combination of opioids, non-opioids, and/or local anesthetics to relieve acute pain, usually postoperative pain.
- Assess for sedation in patients receiving PCA or epidural medication.
- Common adjuvant analgesics, as an addition to other drug regimens, are listed in Table 5-4.
- Nonpharmacologic therapies for pain management may be used in place of or in combination with drug therapy; these therapies are classified as physical measures or cognitive-behavioral therapies.
- Examples of physical measures to manage pain are transcutaneous electrical nerve stimulation (TENS), heat, cold, and massage.
- Distraction, imagery, relaxation techniques, and hypnosis are examples of cognitive-behavioral therapies.
- Acupuncture, magnet therapy, and herbal supplements are examples of other complementary and alternative therapies used for chronic pain management.
- Pain can be managed in any setting, including the home. Some patients require parenteral pain medications at home; therefore provide health teaching to ensure continuity of care.
- Refer patients whose pain is difficult to manage to pain specialists and/or pain centers.

Genetic Concepts for Medical-Surgical Nursing

Answer Key for NCLEX Examination Challenges and
Decision-Making Challenges

Audio Glossary

Key Points

Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Coordinate with health care team members and genetics professionals when providing genetic testing information to patients and families.
2. Advocate for the patient with regard to whether or not to have genetic testing, informed consent before testing, and sharing of test results.
3. Ensure that confidentiality of genetic test results is maintained by all health care team members.

Health Promotion and Maintenance

4. Teach the patient and family who are at increased genetic risk for a disease or disorder to implement environmental modifications to reduce risk.

Psychosocial Integrity

5. Assess patient and family responses to the findings of genetic testing.

6. Support the decision of the patient and family to have or not to have genetic counseling or testing.

Physiological Integrity

7. Compare the concepts of phenotype and genotype.
8. Compare the patterns of inheritance for single gene traits.
9. Explain how genetic variations can affect adult health problems and their management.
10. Construct a three-generation pedigree from data obtained during the family history section of patient assessment.
11. Identify patients at increased genetic risk for health problems.
12. Explain how genetic testing is different from other laboratory tests.
13. Describe the role of the medical-surgical nurse in genetic counseling.

Genetics, *genomics*, and *genomic health care* are common terms in health care today. **Genetics** is concerned with the general mechanisms of heredity and the variation of inherited traits. The definition of **genomics** is both broader and more specific, focusing on the function of all of the human DNA, including genes and noncoding DNA regions. **Genomic health care** is the application of known genetic variation to enhance health care to individuals and their families.

How does genomic health care relate to medical-surgical nursing? Many adult-onset health problems have a genetic basis, meaning that genetic variation at the cellular level

contributes to the person's risk for disease development. Some of these health problems also demonstrate **heritability**, meaning that the risk for developing the disorder can be transmitted to one's children in a recognizable pattern. Some adult-onset disorders, such as Huntington disease, are unavoidable when a person inherits a specific genetic mutation that causes the disorder. For other health problems, the risk is increased but is not absolute, indicating a predisposition or susceptibility toward the problem when a specific genetic mutation is inherited. Such a disorder may never occur, depending on what additional environmental factors

interact with the increased genetic risk. For example, certain gene variations increase the risk for type 2 diabetes in some people; however, the disease is much more likely to develop only when the person with the genetic variation has a sedentary lifestyle and is overweight. Thus, although obesity is not good for anyone, it is clearly more dangerous for some people than others. One outcome of genomic health care is to identify personal risk for disease development and assist the person to reduce the risk by modifying his or her environment.

Although not everything is known about human genomics, specific discoveries regarding each person's genetic differences are being used to assess disease risk, enhance disease prevention strategies, and personalize disease management approaches. As a result, all health care professionals, including registered nurses, are expected to have at least a minimum knowledge of basic genetics to provide the best possible care for patients and families. Professional organizations, such as the American Nurses Association, the American Association of Colleges of Nursing, the American Academy of Nursing, and the National League for Nursing, as well as many specialty nursing organizations, support this position. These groups have agreed with the competencies established by the National Coalition for Health Professional Education in Genetics (NCHPEG) as the minimum essential genetic competencies required for safe nursing practice and have defined additional selected competencies. Table 6-1 lists selected genetic competencies considered particularly important in medical-surgical nursing.

The purpose of this chapter is to build on what you have learned about basic genetics in your science classes and to apply this information to adult health care. Although nurses are not expected to be genetic experts, they need to know enough about basic genetics to recognize when a patient or family has a possible genetic risk for a health problem and to coordinate the attention of health care team members to ensure appropriate care.

GENETIC BIOLOGY

Genes are the instructions for the making of all the different substances the human body produces. Think of all the hormones, enzymes, and other proteins the human body makes. It is the specific genes that tell each cell what protein to make, how to make it, when to make it, and how much to make. Think of each gene as a specific “recipe” for making a protein.

Most genes (more than 99%) are located in the nucleus of body cells. An important fact to remember is that every human cell with a nucleus contains the entire set of human genes. This complete set of genes is called the **genome**. (Mature red blood cells do not have a nucleus and thus contain no genes.) The human genome contains between 20,000 and 25,000 genes. For example, all cells have the gene for insulin. However, even though all cells have the gene for insulin, the only cell type that allows the insulin gene to be active and make insulin is the beta cell of the pancreas. So, although the insulin gene is present in skin cells, heart cells, brain cells, and other cells, only in the beta cells is this gene selectively “turned on” (**expressed**) when insulin is needed.

Genes are composed of DNA, which is present as 46 separate large chunks within the nucleus (Fig. 6-1). During cell

TABLE 6-1 SELECTED ESSENTIAL GENETIC COMPETENCIES FOR MEDICAL-SURGICAL NURSING PRACTICE

- Use appropriate genetic terminology.
- Recognize that a person/family with an identified genetic variation is a full member of society deserving of the same quality of health care as that provided to all others.
- Differentiate between genetic predisposition to a health problem and the actual expression or diagnosis of the health problem.
- Recognize the genetic and environmental influences on development of common adult-onset health problems.
- Be aware of genetic-based individual variation in responses to drug therapy.
- Consider genetic transmission patterns when performing a detailed patient and family history assessment.
- Ask appropriate questions during assessment to obtain information relevant to potential genetic risk or predisposition to a specific health problem(s).
- Construct a family pedigree, using standard symbols, that encompasses at least three generations.
- Identify patients/families at increased genetic risk for potential disease development.
- Ensure that patients/families identified to be at increased genetic risk for potential disease development are referred to the appropriate level of genetics professional.
- Individualize patient teaching about genetic issues using terminology and language the patient/family understands.
- Inform patients/families about potential risks and potential benefits of genetic testing.
- Advocate for patients with regard to their rights of accurate information, informed consent, competent counseling, refusal of genetic testing, freedom from coercion, and sharing of testing results.
- Assist patients/families to find credible resources regarding a specific genetic issue.
- Maintain patient/family confidentiality regarding any issue related to genetic testing, genetic predisposition, or genetic diagnosis, including whether genetic testing is even being considered.
- Support the patient's/family's decisions regarding any aspect of genetic testing or genetic diagnosis.

Adapted from competencies identified by American Association of Colleges of Nursing. (2008). *The essentials of baccalaureate education for nursing practice*. Washington, DC: Author; American Nurses Association. (2008). *Essentials of genetic and genomic nursing: Competencies, curricula guidelines, and outcome indicators* (2nd ed.). Silver Springs, MD: Author; National Coalition for Health Professional Education in Genetics. (2007). Core competencies in genetics for health professionals (3rd ed.). Retrieved October 2010, from www.nchpeg.org/core/core_comps_english2007.pdf.

division, each large chunk of DNA replicates and then organizes into a chromosome form to ensure precise delivery of the genetic information to each of the two new daughter cells. Thus DNA, chromosomes, and genes are all the same basic thing; only the structures differ.

Each chromosome has many genes within it. Humans have 23 pairs of chromosomes—46 individual chromosomes. The Y chromosome, a small chromosome, has fewer than 100 genes. Larger chromosomes, such as the number 1 chromosome, contain thousands of genes.

One way to think of it is to consider all the DNA in any cell's nucleus to be a giant “cookbook” containing all the recipes needed to make all the proteins, hormones, enzymes, and other substances your body needs. The chromosome pairs are the different book chapters (so the human genome cookbook has 23 chapters), and the genes are the individual recipes contained within the chapters.

FIG. 6-1 The various forms of DNA from loose to coiling DNA tightly into a chromosome. *bp*, Base pair.

There is a specific chromosome location (**locus**) for every gene. For example, the locus for the gene for blood type is on chromosome 9. The locus for the gene for part of hemoglobin is on chromosome 11. We now know the location and the exact DNA sequence for many, but not all, genes.

DNA

DNA Structure

In humans, DNA is a linear, double-stranded structure composed of multiple units of four different nitrogenous bases, each attached to a sugar molecule. The bases in each strand are linked together by phosphate groups. These two individual strands are held together loosely. This double-stranded DNA is arranged like a long set of railroad tracks. The “backbones” of the track are the two long steel rails. For DNA, these backbones are the phosphate groups that hold the bases in place. The bases are the individual railroad ties. Think of each tie as having two pieces—one piece attached to the right-hand rail and one piece attached to the left-hand rail.

Fig. 6-2 shows a very small piece of double-stranded DNA on the left (containing only four base pairs) taken from the larger piece of DNA on the right. The phosphate groups that hold the nucleotides together as a strand are in the red box. The green box in the lower left-hand section shows a whole nucleotide (a base with the sugar and the phosphate group) in place in the left-hand DNA strand. The blue box in the

FIG. 6-2 The structure of DNA.

middle of the two strands shows how the base from the left strand lines up with and pairs to a complementary base in the right strand.

Bases are the essential parts of DNA. Many trillions of bases in the DNA are found in the nucleus of just one cell. In fact, if a cell could be cracked open like an egg and the nucleus (yolk) extracted and opened, the amount of DNA in the nucleus, stretched out, would be about 6 feet long. If the DNA in one cell could be made large enough to see and touch (about the width of a tape measure), it would be long

FIG. 6-3 Close view of DNA with four bases converted into nucleotides held loosely together by hydrogen bonds forming complementary base pairs. — — — = weak hydrogen bonds.

FIG. 6-4 Complementary strands of DNA.

enough to stretch out more than 1000 feet! There is much more DNA in each nucleus than is needed for the 25,000 genes. The gene DNA makes up only about 5% of all the DNA in each cell.

The four bases in DNA are adenine (A), guanine (G), cytosine (C), and thymine (T). Each base becomes a complete **nucleotide** when a five-sided sugar (known as a *deoxyribose sugar*) and a phosphate group are attached (Fig. 6-3). Nucleotides form the DNA strands with the phosphate groups holding the bases in place.

Base pairs are the linked bases in the two opposite strands of DNA. The bases always link together across from each other in a very specific way. Thymine always forms a pair with adenine, and cytosine always forms a pair with guanine. Thus the bases of each pair are complementary to each other. Because these complementary base pairs in DNA are specific, if the base sequence of one strand of DNA is known, the opposite strand's sequence could be accurately predicted. For example, if the left-hand section of DNA (strand 1 in Fig. 6-4) had the sequence A-G-G-C-T-C-A-A-C-C-T-G,

FIG. 6-5 DNA replication. Blue type, Original DNA; red type, newly replicated DNA.

the corresponding (complementary) right-hand section (strand 2 in Fig. 6-4) of DNA would have the sequence T-C-C-G-A-G-T-T-G-G-A-C.

When the two strands of DNA are lined up properly, they twist into a loose helical shape (see Fig. 6-1). In this shape, the DNA is so fine that it can be seen only with electron microscopes. Only when a cell begins to divide (i.e., undergoes mitosis) does the DNA super-coil tightly into dense pieces called *chromosomes* (see Fig. 6-1), which can be seen with standard microscopes.

DNA Replication

DNA must reproduce itself (**replicate**) every time a cell divides. Cell division (**mitosis**) occurs in a regulated pattern known as the *cell cycle*. The purpose of mitosis is for one cell to reproduce into two new cells, each of which is identical to the cell that started mitosis. For each new cell to have exactly the right amount of DNA and genes, the DNA in the dividing cell must exactly replicate. This process involves having the double strands of DNA separate and then enzymes read the sequence of the original strands and build two new strands that are perfectly complementary to the original strands (Fig. 6-5).

When DNA synthesis is complete, the result is two sets of double-stranded DNA. Each of the two sets has one old strand and one new strand. At the time of actual cell division with the separation into two new cells, one set of DNA will move into one of the two new cells made during mitosis and the second set will move into the other new cell. In this way, every new cell ends up with exactly the right amount of DNA with all the genes.

FIG. 6-6 A single metaphase chromosome.

Chromosomes

As shown in Fig. 6-1, a chromosome is a specific large chunk of highly condensed double-stranded DNA, with each chunk containing billions of bases and hundreds (and sometimes thousands) of genes. Each chromosome forms and moves to the center of the cell that is about to divide. Just before the cell splits into two cells, each chromosome is pulled apart so that half of each chromosome goes into one new cell and the other half goes into the other new cell. Thus chromosomes are temporary structures, but their job is important: precise delivery of DNA to the two new cells. Humans have 46 chromosomes divided into 23 pairs. This number is the “diploid” number of chromosomes for humans.

Fig. 6-6 shows a metaphase chromosome. The “pinched in” area of the chromosome is the centromere. Each left and right half of the chromosome is a chromatid. The “arms” above the centromere are the short arms, or the “p” arms. The longer arms (not legs) below the centromere are the “q” arms. A particular gene may be listed as located on 9q, meaning that the gene has its location (**locus**) on the long arm of the number 9 chromosome.

Some things about a person can be known by examining his or her chromosomes. It is important to remember that the information that can be obtained by chromosomal analysis is limited because each chromosome is composed of a large chunk of DNA. Only very large deletions, additions, or rearrangements of DNA show up at the level of the chromosome. Losses or gains of just a few bases (or even tens of thousands) cannot be detected by chromosome analysis.

A **karyotype** is an organized arrangement of all of the chromosomes present in a cell during the metaphase section of mitosis (Fig. 6-7). A picture of the chromosomes is made. Chromosomes are first paired up and then arranged according to size (largest first) and centromere position. This gross organization of DNA can be used to determine missing or extra whole chromosomes and some large structural rearrangements. A *missing gene or a mutated gene would not show up at this level of analysis.* What can be learned about the

person from whom the karyotype in Fig. 6-7 was made is that the person is human, female, and **euploid** (has the correct number of chromosome pairs for the species). This person is chromosomally “normal,” although she might have one or more genes that are mutated. If the karyotype is abnormal in any way (had more or less than the normal number or had broken chromosomes), the karyotype would be called **aneuploid**.

Autosomes are the 22 pairs of human chromosomes (numbered 1 through 22) that do not code for the sexual differentiation of a person. Autosomal chromosomes contain genes that code for all the structures and regulatory proteins needed for normal function. **Sex chromosomes** are the pair of chromosomes that include the genes for the sexual differentiation of the person. Chromosomally normal males have an X and a Y as the sex chromosomes. Chromosomally normal females have two XXs as the sex chromosomes (see Fig. 6-7).

Gene Structure and Function

A **gene** is a specific segment(s) of DNA that contains the code (recipe) for a specific protein (see Fig. 6-1). One gene usually codes for one protein; thus genes are the smallest functional unit of the DNA. Each chromosome contains hundreds of genes (and each chromosome is made up of a large segment of DNA). Thus an individual gene is a very small segment of DNA.

For many human traits, one gene controls the expression of that trait in any person. Such traits are known as “single gene traits” (monogenic traits). For each single gene, we have two alleles. An **allele** (pronounced “ah-lee-el”) is an alternate form (or variation) of a gene. For example, there is one gene for blood type but there are three possible gene alleles (A, B, and O). Each person has only two of the three specific gene alleles for blood type. One of these alleles is on one chromosome 9 of the pair; the other allele is located on the other number 9 chromosome. Because each person only has two number 9 chromosomes, he or she can have only two alleles for blood type. One gene allele was inherited from the person’s mother, and the other gene allele was inherited from the person’s father. *Some traits have even more than three possible alleles, but each person has only two.* Which blood type gene alleles are inherited from a person’s parents determines which blood type he or she expresses.

If a person has inherited a blood type A allele from his or her mother and a blood type B allele from his or her father, he or she has the A and B alleles; the blood type expressed when the blood bank determines type is type AB. Fig. 6-8 shows this concept. In Fig. 6-8, two people are about to become pregnant. What are the possibilities for this baby to have a specific type of ear shape (pointy, rounded, square, triangular)? The gene for ear shape is trait 1, and it (for the purposes of this explanation) is on chromosome number 6.

Each of the father’s sperm contains only one number 6 chromosome, and each of the mother’s eggs contains only one number 6 chromosome (so that when the sperm fertilizes the egg, the resulting person conceived will have only one pair of chromosome number 6 instead of two pairs of chromosome number 6). In Fig. 6-8, the paternal chromosomes are represented in blue and the maternal chromosomes are represented in pink. Throughout this text, when single gene health problems are described using either

FIG. 6-7 A karyotype of a chromosomally normal female. (The sex chromosomes are circled in red.)

FIG. 6-8 Inheritance of four possible alleles for the single gene trait 1. (Any one person can have only two alleles for a single gene trait.)

a chromosome depiction or a Punnett square depiction, paternal genetic input is represented in blue and maternal genetic input is represented in pink.

Half the father's sperm have the 1a allele for ear shape, and the other half have allele 1b for ear shape. Half the

mother's eggs have 1c for ear shape, and the other half have 1d. The resulting baby can inherit only a 1a or a 1b from the father, not both; and this same baby can inherit only a 1c or a 1d from the mother—again, not both. The lower portion of Fig. 6-8 shows all the combinations possible for each ear shape gene alleles for any child these two people have.

If a person has two identical alleles for a single gene trait, that person is said to be *homozygous* for that trait. So if a person has an A blood-type gene allele on one number 9 chromosome and an A blood-type gene allele on the other number 9 chromosome, he or she is homozygous for that trait and will express the A blood type.

If a person has two different alleles for a single gene trait, he or she is *heterozygous* for that trait. So if a person has an A blood-type gene allele on one number 9 chromosome and a B blood-type gene allele on the other number 9 chromosome, that person is heterozygous for that trait and will express the AB blood type. Because the A and B alleles are equally dominant (*co-dominant*), they will both be expressed in the actual blood type.

There are differences in expression of the alleles for a trait depending on whether an allele is dominant or is recessive. If a person has an A blood-type gene allele on one number 9

chromosome and an O blood-type gene allele on the other number 9 chromosome, that person is heterozygous for that trait and expresses only the A blood type. Because the A allele is dominant and the O allele is recessive, they will not both be expressed in the actual blood type. Only the dominant allele is expressed, and the recessive allele is “silent.” More information about dominant, recessive, and co-dominant expression is presented later in the “Patterns of Inheritance” section on p. 72.

Phenotype

The **phenotype** of any gene for a person is what characteristic can actually be observed or, in some cases, determined by a laboratory test. For example, the person who has the AO gene alleles for blood type has the phenotype of type A blood. A person with curly hair has a curly hair phenotype regardless of whether he or she has two alleles for curly hair or one allele for curly hair and one allele for straight hair.

Genotype

The **genotype** for a person’s single gene trait is what the actual alleles are for that trait—not just what can be observed. A person with a phenotype of type A blood could have either an AA genotype or an AO genotype. The person who has type O blood would have an OO genotype. When a person has homozygous alleles for a trait, we would expect the genotype and phenotype to be the same. When a person has heterozygous alleles for a trait, the phenotype and the genotype are not always the same. *Recessive traits are expressed only when the person is homozygous for the alleles.* Thus for expressed recessive traits, phenotype and genotype are the same. Dominant traits are expressed whether the person is homozygous for the gene alleles or heterozygous for the gene alleles. Thus for dominant traits, phenotype and genotype can be the same but do not have to be the same.

Gene Expression

The purpose of a gene is to code for the making of a specific protein used by a cell, tissue, or organ within a person. For example, the hormone *insulin* is a protein. When a person’s blood glucose level starts to rise, the beta cells of the pancreas rapidly make insulin to meet the immediate needs of the person for blood glucose homeostasis.

To continue the cookbook analogy, each gene is the recipe needed to make a specific protein. All the “stuff” that a human body makes—every hormone, every enzyme, every growth factor, every chemical needed to keep the person functioning—is a protein. These proteins are *gene products* because they are produced when the right gene is “turned on” or *expressed*. Just a few examples of gene products are insulin, hemoglobin, erythropoietin, angiotensin, and estrogen.

Protein Synthesis

Protein synthesis is the process by which genes are used to make the proteins needed for physiologic function. Remember from your science classes, proteins are made up of individual amino acids hooked together like beads on a string. There are 22 different amino acids. Every protein has a specific number of each of the amino acids and a specific order in which they are placed. *If even one amino acid is out of order or completely deleted from the sequence, the protein will be less*

functional or, perhaps, nonfunctional and unable to perform its job in the body.

For example, the hormone *insulin* is a protein that contains 51 amino acids in a specific sequence. If some of the amino acids are missing or are in the wrong position, the protein made would be different from real insulin and could not reduce blood glucose levels. *Thus the actual order of the amino acids is critical for the final function of any protein.*

Within the DNA there is a code for each amino acid (Table 6-2). Each amino acid code is three bases (nucleotides) long. A gene is the recipe for making a specific protein. It contains all the amino acid codes in exactly the right order for that protein. For example, the final active form of the protein *insulin* has 51 amino acids. Thus the minimum number of bases needed in the gene for insulin would be 153 (3 bases per amino acid $\times$ 51 amino acids). Fig. 6-9 shows an example of a short protein made up of only 7 amino acids.

The process of making proteins involves first identifying the gene and copying it into messenger RNA (transcription), and then translating the message in the RNA into the actual protein. To think of this process in terms of the cookbook, the entire genome in each cell is the giant cookbook in the library. When a specific protein needs to be made, the chapter for that protein is opened (the chromosome) and the right recipe is found (the gene). The recipe is copied (transcribed) onto a note card (messenger ribonucleic acid, or mRNA) and taken to the kitchen (endoplasmic reticulum). In the kitchen, all the ingredients (amino acids) are put together (translated) in the right order with the help of bowls, ovens, pans, potholders, and other kitchen tools (adapter and transfer molecules). The key for making a functional protein is accurate placement of all the amino acids in the order specified by the gene. When problems exist in the base sequence of a gene, its expression may not result

TABLE 6-2 EXAMPLES OF DNA CODES AND RNA CODONS FOR SELECTED AMINO ACIDS

AMINO ACID	DNA CODE(S)	RNA CODONS
Alanine	CGA, CGG, CGT, CGC	GCU, GCC, GCA, GCG
Glycine	CCA, CCG, CCT, CCC	GGU, GGC, GGA, GGG
Isoleucine	TAA, TAG, TAT	AUU, AUC, AUA
Lysine	TTT, TTC	AAA, AAG
Tryptophan	ACC	UGG
Tyrosine	ATA, ATG	UAU, UAC
Start		AUG
Stop		UAA, UAG, UGA

FIG. 6-9 A sample protein composed of seven amino acids. The RNA codons for the individual amino acids are listed below each amino acid.

in a functional protein. In addition, the process of protein synthesis involves many complex steps and a problem at any step could result in the failure to produce a functional protein.

Mutations

Many human genes have been sequenced, meaning that their base sequence is known and so is the sequence of their amino acids in the expressed proteins. Most people have the same base sequence for a specific gene, like the gene for insulin. When this sequence is the most common one found in a large population of humans, it is referred to as the *wild-type* gene sequence. Think of the term *wild-type* as meaning “normal” or “expected.” When a person has a different sequence for a gene compared with the known wild-type sequence, the gene has a variation or mutation. Mutations as small variations in gene sequences are more common for very large genes (which may contain more than a million bases), and the significance of some of these changes is not known. It is these differences or variations in the sequences of some genes that are now being considered in health care.

Mutations are DNA changes that are passed from one generation to another and thus are *inherited*. An inherited mutation does not have to mean that the mutation is passed from one human generation to another. It can mean that the mutation is passed from one *cell* generation to another and may affect only certain tissues within a person rather than be a problem within a family. These mutations occur in general body cells (somatic cells) and are known as *somatic mutations*. Because these mutations occur in a person's cells after conception, the person cannot pass a somatic mutation on to his or her children. One possible outcome of somatic mutations is an increased risk for cancer in cells with such mutations.

When mutations occur in sex cells, they are called *germline mutations*. A germline mutation can be passed on to a person's children, and each of that child's cells, including his or her somatic cells, will contain the mutated DNA.

DNA bases can be altered or “mutated” accidentally. Sometimes the wrong base is put into a certain position in the newly made DNA strand during cell division. It is also possible for a base to be accidentally deleted or an extra base placed into the strand. Usually most errors that occur during the making of DNA are corrected at that time, although some changes probably occur daily and escape correction in any one person. If these changes occur in a gene area of the DNA, the change can alter the expression of that gene and an incorrect gene product (protein) might result. So mutations can have serious results, although some mutations may actually be beneficial. Gene mutations or variations that increase the risk for a disorder are known as *susceptibility* genes. Gene mutations or variations that decrease the risk for a disorder are known as *protective* or *resistance* genes.

As stated earlier, the gene sequences for most proteins are generally the same in all people. Sometimes a base in one person's gene for a specific protein is not the same as that in the wild-type. Either this difference can be a variation known as a *single nucleotide polymorphism*, or *SNP* (“snip”), or it can be a mutation. When a base difference allows the protein to be made but there are differences in how well the protein works, the difference is called a *variation* or a **polymorphism**.

When a base difference causes a loss of protein function, it is called a **mutation**. The two types of mutations are point mutations and frameshift mutations.

Point Mutations

Point mutations are the substitution of one base for another. A change has been made at a single point of DNA, and the type of change is a base substitution, not a deletion or addition. So the triplets, or three-base codes, remain intact, although one may be incorrect. This change may or may not alter amino acid position or protein synthesis.

Below is an analogy to a point mutation. The top sentence represents the “reading sequence” for a specific gene:

THE BIG DOG ATE THE CAT
THE BIG DOG ATE THE CAP

A point mutation, as seen in the bottom sentence, has changed the *t* in cat to a *p*. The coded message is similar but not exactly the same.

Sometimes a point mutation can change the protein (gene product) a little but it can still function. Sometimes, however, a point mutation changes the protein just enough that it does not work at all. It all depends on how critical the amino acid that changed was to the function of the protein.

Clinically, many SNPs exist within different people in the genes of a large family of enzymes involved in drug metabolism. These enzymes are the cytochrome P-450 family, coded for by at least ten separate extremely large genes, with as many as 100 subsets of genes. Cytochrome p is abbreviated as CYP (pronounced “sip”). SNPs in these genes can make the resulting enzyme less active than normal or more active than normal. Either way, a change in activity of any one of these enzymes can affect a person's response to drug therapy. For example, the drug *warfarin* (Coumadin) is metabolized for elimination primarily by two enzymes from this system, CYP2C9 and CYP2C19. About 17% to 37% of white people have a SNP variation in CYP2C9 that slows the metabolism of warfarin. This means that warfarin remains in the person's system longer, greatly increasing the risk for bleeding and other side effects. For people who have this gene mutation, warfarin doses need to be much lower than those for the general population.

CULTURAL AWARENESS

Most people of Asian heritage have a SNP in the *CYP2C19* gene that results in low activity of the enzyme produced. This mutation greatly reduces the metabolism of warfarin, leading to increased bleeding risks and other serious side effects. Any person of Asian heritage who needs anticoagulation therapy should be started on very low dosages of warfarin and have his or her international normalized ratio (INR) monitored more frequently than people who do not have a variation of the *CYP2C19* gene.

Frameshift Mutations

Frameshift mutations are those that occur as a result of adding or deleting a single base or a group of bases. This type of mutation always alters amino acid position, disrupts the reading frame, and stops protein synthesis. These changes ruin the reading sequence of the gene from the mutation on down. *These changes are very serious because a normal product cannot be made from a gene with such a mutation.*

Below is an analogy to a frameshift mutation. The top sentence represents the correct “reading sequence” for a specific gene:

THE BIG DOG ATE THE CAT
 THB IGD OGA TET HEC AT
 THE PBI GDO GAT ETH ECA T

A base deletion mutation, as seen in the middle sentence, has removed the *E* in “THE,” shifting the rest of the bases to the left (for the three-base codes) and disrupting the reading frame. A base addition mutation, as seen in the bottom sentence, has added a *P* to “BIG,” shifting the three-base reading codes to the right and disrupting the reading frame. The coded message (recipe) has been lost completely.

Changes in genes, even small changes, can have serious results. Some changes would inactivate a protein. Other changes may alter how often or how well a group of cells divides. Gene variations may cause one person to have a greater-than-normal risk for developing a disease. A different variation in the same gene may cause another person to have a smaller-than-normal risk for developing the same disease.

PATTERNS OF INHERITANCE

For every single gene trait, a person inherits one allele for that gene from his or her mother and one allele from his or her father. How these traits are expressed depends on whether one or both alleles are “dominant” or whether one or both alleles are “recessive.” Expression also depends on whether the gene for the trait is located on an autosome or on a sex chromosome.

It is possible to determine how the gene for a specific trait is passed from one human generation to the next (transmitted). By looking at how that trait is expressed through several generations of a family, patterns emerge that indicate whether the gene for the trait is dominant or recessive and whether it is located on an autosomal chromosome or on one of the sex chromosomes. This information can be determined through pedigree analysis. Determining inheritance patterns for a specific trait makes it possible to predict the risk for any one person to have a trait or transmit that trait to his or her children.

Pedigree

A **pedigree** is a graph of a family history for a specific trait or health problem over several generations. Fig. 6-10 shows common symbols used when creating a pedigree. Fig. 6-11 shows a typical three-generation pedigree. Although the term *pedigree* is the correct genetic term, some patients are offended by this term. Use the term *family tree* in place of pedigree when talking with patients. Construct a pedigree that includes at least three generations when taking the family history. When analyzing a pedigree, note the answers to these:

- Is any pattern of inheritance recognized, or does the trait appear sporadic?
- Is the trait expressed equally among male and female family members or unequally?
- Is the trait present in every generation, or does it skip one or more generations?

FIG. 6-10 Standard pedigree symbols.

FIG. 6-11 A three-generation pedigree showing an autosomal dominant pattern of inheritance.

- Do only affected people have children affected with the trait, or do unaffected people also have children who express the trait?

The four types of inheritance patterns associated with single gene-controlled traits are autosomal dominant, autosomal recessive, sex-linked dominant, and sex-linked recessive. Each inheritance pattern has specific defining criteria. Table 6-3 lists the patterns of inheritance for some disorders that either are identified in adults or may be identified in children who live to adulthood.

Some traits and disorders cluster within a family but do not follow any known pattern of inheritance. Although no specific single gene has yet been found for some of these disorders, the clustering suggests a genetic basis. It is thought that for some of the disorders that show familial clustering, environmental factors may modify a genetic predisposition. Continued genetic research may solve the familial clustering gene puzzle.

TABLE 6-3 PATTERNS OF INHERITANCE FOR GENETIC DISORDERS AMONG ADULTS

PATTERN OF INHERITANCE	DISORDER
Autosomal dominant	Breast cancer* (mutation of <i>BRCA1</i> or <i>BRCA2</i> genes)
	Diabetes mellitus type 2*
	Familial adenomatous polyposis
	Familial melanoma
	Familial hypercholesterolemia
	Hereditary nonpolyposis colon cancer (HNPCC)
	Huntington disease
	Long QT syndrome and sudden cardiac death
	Malignant hyperthermia (MH)
	Marfan syndrome
	Myotonic dystrophy
	Neurofibromatosis (types 1 and 2)
	Ovarian cancer* (mutation of <i>BRCA1</i> genes)
	Polycystic kidney disease† (types 1 and 2)
	Retinitis pigmentosa†
	von Willebrand's disease
Autosomal recessive	Albinism
	Alpha ₁ -antitrypsin deficiency
	Beta thalassemia
	Bloom syndrome
	Cystic fibrosis
	Hereditary hemochromatosis
	Sickle cell disease
Sex-linked recessive	Xeroderma pigmentosum
	Glucose-6-phosphate dehydrogenase deficiency
	Hemophilia
Complex disorders/ Familial clustering	Red-green color blindness
	Alzheimer's disease
	Autoimmune disorders
	Bipolar disorder
	Parkinson disease
	Schizophrenia
	Hypertension
	Rheumatoid arthritis

*Some disorders have both a genetic and nongenetic form.

†Some disorders have more than one genetic form and can also be autosomal recessive.

Autosomal Dominant Pattern of Inheritance

Autosomal dominant (AD) single gene traits require that the gene alleles controlling the trait be located on an autosomal chromosome. A dominant gene allele is expressed even when only one allele of the pair is dominant. Other criteria for AD patterns of inheritance include:

- The trait appears in every generation with no skipping.
- The risk for an affected person to pass the trait to a child is 50% with each pregnancy.
- Unaffected people do not have affected children; therefore their risk is essentially 0%.
- The trait is found about equally in males and females.

An example of an AD trait is blood type A. If a person is homozygous for the blood type A allele, he or she will express type A blood (with genotype being identical to the phenotype). If a person is heterozygous for the blood type A allele with the other allele being type O (which is a recessive trait),

he or she will also express type A blood. In this case, however, the phenotype is not identical to the genotype. *When a dominant allele is paired with a recessive allele, only the dominant allele is expressed.* The blood type B allele is a dominant allele. When a B allele is paired with an O allele, B blood type is expressed. When a person has one blood type A allele and a blood type B allele, however, both alleles are expressed (because they are equally dominant) and the person has type AB blood.

When a person actually has a specific gene allele, he or she is said to “carry” that gene allele. This issue is different from being a “carrier” of a recessive allele. Carrier status is discussed in the “Autosomal Recessive Pattern of Inheritance” section on p. 74.

Some health problems inherited as autosomal dominant (AD) single gene traits are not apparent at birth but develop as the person ages (see Table 6-3). Two factors that affect the expression of some AD single gene traits are penetrance and expressivity.

Penetrance

Penetrance is how often or how well, within a population, a gene is expressed when it is present. Some genes are more penetrant than others. For example, the gene for Huntington disease (HD) has an autosomal dominant pattern of transmission. Therefore a person who has one HD allele is at risk for developing HD. This gene is “highly penetrant” (sometimes called “fully penetrant”). This means that if a person has the HD gene allele, his or her risk for expressing the gene and developing the disease is about 99.99%.

Some dominant gene alleles have “reduced” penetrance. This means that a person who has the gene mutation has a lower risk for this gene being expressed and actually developing the disorder.

Penetrance is calculated by examining a population of people known to have the gene mutation and assessing the percentage that go on to express the gene by developing the disorder. For example, the *BRCA2* gene mutation increases a person's risk for breast cancer. This gene is not fully penetrant, so some women (and men) who have the gene do not develop breast cancer. The penetrance rate for this gene mutation is calculated to be between 60% and 80%, meaning that a person who has the gene mutation has a 60% to 80% risk for developing breast cancer. Although this risk is far higher than among people who do not have the mutated gene, the risk is not 100%. Having the gene mutation does not absolutely predict that the person will develop breast cancer—just that the risk is high.

Expressivity

Expressivity is the degree of expression a person has when a dominant gene is present. So it is a personal issue, not a population issue. The gene is *always* expressed, but some people have more severe problems than do other people. For example, the gene mutation for one form of neurofibromatosis (NF1) is dominant. Some people with this gene mutation have only a few light brown skin tone areas known as *café au lait spots*. These skin lesions can be so minor that the person may not even be aware that they are present. Other people with the same gene mutation develop hundreds of tumors (neurofibromas) that protrude through the skin. Expressivity accounts for some variation in genetic disease severity.

FIG. 6-12 A typical pedigree showing an autosomal recessive pattern of inheritance.

Autosomal Recessive Pattern of Inheritance

Autosomal recessive (AR) single gene traits require that the gene controlling the trait be located on an autosomal chromosome. The trait can be expressed *only* when both alleles are present. Table 6-3 lists some AR adult disorders. Fig. 6-12 shows a typical pedigree for an AR disorder. Criteria for AR patterns of inheritance include:

- The trait may not appear in all generations of any one branch of a family.
- The trait often first appears only in siblings rather than in the parents.
- About 25% of a family will be affected and express the trait.
- The children of two affected parents will *always* be affected (risk is 100%).
- Unaffected people who are carriers (heterozygous for the trait) and do not express the trait themselves *can* transmit the trait to their children if their partner either is also a carrier or is affected.
- The trait is found about equally in male and female members of the same family.

An example of an AR trait is type O blood. The blood-type O allele is recessive, and both alleles must be type O (homozygous) for the person to express type O blood. If only one allele is a type O allele and the other allele is either type A or type B, the dominant allele will be expressed and the O allele, although present, is not expressed. For AR single gene traits, phenotype and genotype are always the same.

A person who has one mutated allele for a recessive genetic disorder is a **carrier**. A carrier, even though he or she may have one mutated allele, does not usually have any manifestations of the disorder but can pass this mutated allele on to his or her children. For some autosomal recessive disorders, a carrier may have very mild manifestations. One example is sickle cell trait. A person with two sickle cell alleles has the disease and has many associated health problems. A carrier with one sickle cell allele (has “sickle cell trait”) may be healthy most of the time and have manifestations only under conditions of severe hypoxia.

Sex-Linked Recessive Pattern of Inheritance

Some genes are present only on the sex chromosomes. The Y chromosome has only a few genes that are not also present on the X chromosome. These few genes are important for male sexual development. The X chromosome, however, has many single genes that are not present on the Y or elsewhere in the human genome. Some of these genes are specific for female sexual development, but there are also several hundred genes on the X chromosome that code for other

FIG. 6-13 A typical pedigree showing a sex-linked (X-linked) recessive pattern of inheritance.

functions. Few traits or disorders have an X-linked dominant pattern of expression, and they are not discussed in this chapter.

Because the number of X chromosomes in males and females is not the same (1:2), the number of X-linked chromosome genes in the two genders is also unequal. Males have only one X chromosome. As a result, X-linked recessive genes have dominant expression in males and recessive expression in females. This difference in expression is because males do not have a second X chromosome to balance the presence of a recessive gene on the first X chromosome.

Sex-linked (X-linked) recessive single gene traits require that the gene allele be present on both of the X chromosomes for the trait to be expressed in females (homozygous) and on only one X chromosome for the trait to be expressed in males. Fig. 6-13 shows a typical pedigree for a sex-linked recessive disorder. Features of a sex-linked recessive pattern of inheritance include:

- The incidence of the trait is much higher among males in a family than among females.
- The trait cannot be passed down (transmitted) from father to son.
- Transmission of the trait is from father to all daughters (who will be carriers).
- Female carriers have a 50% risk (with each pregnancy) of passing the gene to their children.

Complex Inheritance and Familial Clustering

Some health problems appear in families at a rate higher than normal and greater than can be accounted for by chance alone; however, no specific pattern occurs within a family. Although clusters suggest a genetic influence, it is likely that additional factors, such as gender and the environment, also influence disease development or disease severity. Such disorders include Alzheimer’s disease, type 1 diabetes, and many others. These disorders are often called *complex* and *multifactorial*, because although an increased genetic risk may be present, the risk is changed by diet, lifestyle, exposure to toxins, infectious agents, and other factors.

GENETIC TESTING

Purpose of Genetic Testing

Many people are eager to have genetic testing but also are fearful of genetic testing. The lay public often believes that a single genetic test can “tell everything about a person.”

Although genetic testing has the potential to be that informative, this is not currently the case. *It is important to remember that no single person is genetically perfect.*

Genetic testing can be performed with many different techniques. Some genetic tests are specific for a disorder. Others may show a gene variation but the significance of the variation may not be known. Unexpected information can be found during genetic testing. Some ordinary tests, such as blood typing and tissue typing, provide genetic information. Tests that measure the amount of an enzyme or protein also provide genetic information.

Actual genetic testing can be performed at many levels. Cellular or biochemical tests provide information about gene products made by a cell, tissue, or organ. Chromosomes can be assessed for missing, extra, or broken chromosomes. Chromosome segments can be analyzed for abnormalities or changes from normal positions. The sequence of a gene can be examined to determine variation or mutation. At present, not all genes can be analyzed and the analysis of even one gene is limited by expense and availability. Specific base pairs can be evaluated for mutations. These tests are expensive, and the results may not be conclusive. Table 6-4 lists purposes of genetic testing for adults.

Benefits and Risks of Genetic Testing

Genetic testing is different from any other type of testing for many reasons. *It is important to remember that just because the technology exists does not mean it should be used in all cases.* Informed consent is required before genetic testing is undertaken. The person tested is the one who gives consent, even though genetic testing *always* gives information about a family and family members—not just the patient.

Benefits of genetic testing include the ability to confirm a diagnosis or to test people who are at risk for a health problem but do not as yet have any symptoms (presymptomatic testing). The information can help a person, family, and their health care provider develop a specific plan of care or early detection. For example, in the case of a strong genetic predisposition for colon cancer, identifying a patient before symptoms appear allows interventions to prevent the disease or to diagnosis it earlier, when cure is more likely.

Risks are associated with genetic testing that are not associated with other types of tests. Genetic testing results do not change. This means that a positive test result cannot be “taken back.” The risks of genetic testing may include psychological or social risks, as well as a risk for family disruption. Often genetic tests are expensive and may not be covered by insurance. Some genetic tests have limited value for predicting future risk. Testing may identify a patient at great risk for the future development of a serious health problem that cannot be prevented. Such a disorder is Huntington disease (HD), which currently has no treatment. Knowing positive test results in this case can lead to depression, blame, and guilt.

Another risk of genetic testing is that positive results may be used to discriminate against a person or a family. Some protection is in place to prevent health insurance companies from failing to insure a person or dropping the coverage of a person who is at high risk for developing a serious illness (e.g., breast or ovarian cancer). However, there are no protections against rate hikes or exclusions of specific treatments. Patients often fear workplace

TABLE 6-4 PURPOSES OF GENETIC TESTING FOR ADULTS

PURPOSE/TYPE	DEFINITION
Carrier testing	Determining whether a patient without symptoms has an allele for a recessive disorder that could be transmitted to his or her children. Disorders for which carrier testing is common include sickle cell disease, hemophilia, hereditary hemochromatosis, cystic fibrosis, beta thalassemia, and Tay-Sachs disease.
Diagnostic testing	Determining whether a patient has or does not have a mutation that increases the risk for a specific disorder.
Symptomatic	Patient has clinical manifestations; test results confirm a diagnosis.
Presymptomatic	Patient has no clinical manifestations but is at high risk for inheriting a specific genetic disorder for which there is no known prevention or treatment. A disorder for which presymptomatic testing is commonly performed is Huntington disease.
Predisposition	Family history or genetic testing indicates risk is high for a known genetic disorder. The patient does not have any manifestations but wants to know whether he or she has the specific mutation and what the chances are that it will be expressed. Disorders for which predisposition testing is often performed include hereditary breast/ovarian cancer and hereditary colorectal cancers. The advantage of predisposition testing is that the patient can then engage in heightened screening activities or medical and surgical interventions that reduce risk.

discrimination and personal discrimination if positive test results become known.

Genetic Counseling

Genetic testing is not a standard test that any person should have performed without knowing the advantages and disadvantages. Counseling patients before, during, and after testing is critical. Entire families may be a part of the genetic evaluation and follow-up. For example, a 45-year-old woman has breast cancer. In her family, her mother, grandmother, brother, and one sister have all had breast cancer. Genetic testing indicates that she has a *BRCA1* gene mutation. This woman's older daughter wonders whether she has a gene mutation for breast cancer and asks to be tested. When she and her younger sister are tested, the older daughter does not have the mutation but the younger sister does.

Genetic counseling is a process—not a single session or a single recommendation. This process should begin when the patient or family is first identified as potentially having a genetic problem. The process continues through actual testing if the decision to test is made, and it continues through interpretation of results and follow-up. Steps in the process are listed in Chart 6-1.

As a nurse and patient advocate, determine whether the patient understands the consequences of testing. Often a

CHART 6-1 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Steps for Genetic Testing and Counseling**Pre-Testing Assessment and Patient Education (May Take Multiple Sessions)**

- Determining patient understanding and why testing or counseling is being sought
- Determining whether testing is reasonable (considering cost of the test, specificity, probable risk, accuracy of testing)
- Establishing a trusting professional relationship
- Ensuring privacy and confidentiality
- Reviewing informed consent procedures
- Assessing the patient's ability to communicate accurately (including language issues, cognitive function, sensory perception)
- Assessing the patient's psychosocial status and availability of social support
- Taking a detailed patient health history (including drugs, diet, exercise, hormonal history, lifestyle issues)
- Obtaining physical assessment data relevant to the at-risk disorder
- Taking a detailed family history and constructing a three-generation pedigree (minimum)
- Obtaining and verifying information obtained from:
 - Patient
 - Family members
 - Medical records
 - Pathology reports
 - Death certificates
- Interpreting the family history
- Discussing the consequences of testing

- Discussing patient rights and obligations regarding disclosure of information
- Discussing testing options
- Assessing to determine whether coercion is occurring
- Obtaining material to be tested (usually blood)

Test Result Presentation

- Re-assessing the patient's wish to know or not know the test results
- Respecting the patient's decision not to know the test results
- Ensuring privacy and confidentiality
- Presenting the test results
- Interpreting the test results
- Assessing the patient's perception of the test results

Follow-Up

- Supporting the patient's decision to disclose or not disclose the information to other family members
- Discussing the potential risks for other family members
- Ensuring privacy and confidentiality
- Addressing the patient's concerns
- Discussing prevention, early detection, and treatment options
- Discussing family concerns
- Addressing psychosocial issues
- Discussing available resources for information, support, and further counseling
- Providing summary of results and consultation to the patient

patient may request genetic testing even when there is no indication of an increased risk for a genetic disorder. Counseling and evaluation can help patients understand whether any useful information could be obtained from testing.

Counseling is performed by a professional or a team who have defined expertise in interpretation of genetic testing results. Such professionals include advanced practice nurses with specialization in genetics, certified genetic counselors, clinical geneticists, and medical geneticists. Each profession has a different level of preparation in genetics and different skills or roles in the counseling process. For example, an advanced practice nurse may counsel a patient about the Huntington disease (HD) gene mutation because this test is not ambiguous and the gene is highly penetrant. When a genetic test shows a variation or mutation in an unusual gene region or when penetrance is reduced, the patient may best be served by counseling from a certified genetic counselor or a clinical or medical geneticist.

No matter which professional is involved in genetic counseling, a key feature of this counseling is to be "nondirective." When using a nondirective approach, the counselor provides as much information as possible about the risks and benefits but does not in any way influence the patient's decision to test or not to test. Once the patient has made the decision, the counselor supports the patient and the decision.

Ethical Issues

Many ethical issues are involved with genetic testing. Some of the most important issues focus on the patient's right to know versus the right not to know his or her gene status, confidentiality, coercion, and sharing of information.

The right to know genetic risk versus the right not to know is the individual patient's choice. Sometimes a patient's right

to know has an impact on the right of another family member not to know. For example, if a patient's maternal grandfather had HD and the patient wants to know whether he or she has that gene, he or she is tested. This person's mother does not want to know whether she has the gene. If the patient is tested and found to have the gene, because HD is autosomal dominant, the only way he or she could have the gene is if this person's mother also has it. Thus when the patient finds out he or she is positive and tells the mother, the mother will learn that she is also positive, even if she did not want to know.

Confidentiality is crucial to the genetic counseling process. The results of a genetic test must remain confidential to the patient. The results cannot be given to a family member, other health care provider, or insurance carrier without the patient's permission.

Coercion is possible by other family members and even by health care professionals.

The final decision to have genetic testing or not to have testing rests with the patient. Other people may believe it is important for the patient to have the test; however, the patient must make the decision without such pressures. As a patient advocate, assess whether the patient is freely making the decision to have genetic testing or whether someone else is urging the patient to test. This important issue can be difficult to assess. Ask the patient who else in his or her family wants to know the results of testing. An important question to ask is, Will you do anything differently for screening or treatment if the test is positive versus if the test is negative?

Sharing of test result information, negative or positive, can induce stress. The patient makes the final decision to share the information with family members. Some patients

choose not to share this information even when other family members may also be at risk. This can be difficult for the health care provider who knows the patient has a positive test result for a serious inherited condition and the patient chooses not to tell other family members who may be at risk. For example, hereditary non-polyposis colon cancer (HNPCC) has an autosomal dominant inheritance pattern and each child of the patient has a 50% risk for having the gene. If the patient chooses not to tell his or her grown children, they then do not have the opportunity for increased screening to find the cancer at an early stage when cure is possible. An ethical dilemma arises when the health care provider wants to inform the children of their risk.

THE ROLE OF THE MEDICAL-SURGICAL NURSE IN GENETIC COUNSELING

Medical-surgical nurses help patients during the assessing, testing, and counseling processes in many areas, although they do not provide in-depth genetic counseling. Patients often feel most comfortable sharing information with nurses and asking nurses to clarify information.

Nurses may be the first health care professionals to identify a patient at specific genetic risk. Some of the “red flags” that a patient may have an increased genetic risk for a disease or disorder are:

- The disease or disorder occurs at a higher incidence within the family compared with the general population.
- The patient or close family members have another identified genetic problem.
- The incidence of a specific disease or disorder occurs in the patient or in family members at an unusually early age.
- A rare disease is present in two or more family members.
- More than one type of cancer is present in any one person.
- The specific manifestation is associated with one or more genetic disorders (e.g., unusual freckling or skin pigmentation, bicuspid aortic valve, deafness).

The nurse may be the health care professional who first verifies information to bring a genetic problem to light. For example, during an assessment, a patient reveals that her mother died of bone cancer when she was 40 years old. Bone cancer is quite rare among adults; thus the nurse might then ask, Did your mother ever have any other type of cancer? Often the patient may then reveal that her mother had breast cancer some years before that (“bone cancer” was actually breast cancer that had spread to the bones). Breast cancer at an early age can indicate a genetic predisposition.

Patients may ask questions that indicate they have an interest in genetic testing. These are examples of questions that may be cues that the patient has genetic concerns:

- Will my children get this disease?
- Because my sister has this problem, what are the chances I might also develop it?
- Is there a way to test and see whether my chances of getting this disease or problem are high or low?

Areas of responsibility for any medical-surgical nurse in working with a patient who is considering or having genetic

testing include communication, privacy and confidentiality, information accuracy, patient advocacy, and support.

Communication

Act as a patient advocate by ensuring that communication between the patient and whoever is providing the genetic information is clear. First, assess the patient’s ability to receive and process information. Can the patient see and hear clearly, or are assistive devices needed? Does the patient understand English, or will an interpreter be needed? Does the patient have adequate cognition at the time of meeting with the genetic professional, or is it impaired by medication, disease, anxiety, or fear?

If the patient appears not to understand terms or jargon during a discussion between him or her and a genetic professional, ask the professional to use common terms and examples for the patient. Verify with the patient that he or she understands or does not understand.

After any discussion about genetic risk or genetic testing, assess the patient’s understanding of what was said. Ask the patient to explain, in his or her own words, what the issue means and what his or her expectations are.

Privacy and Confidentiality

All conversations regarding potential diagnoses or genetic testing need to occur in a private environment. The patient has the right to determine who may be a part of the discussion. The patient can decide to exclude his or her primary physician and any family member from the discussion with a genetic professional. It is important that health care professionals who may be present during such discussion do not disclose information, formally or informally, without the patient’s permission. It is the nurse’s responsibility to protect this information from improper disclosure to family members, other health care professionals, other patients, insurance providers, or anyone not specified by the patient.

Information Accuracy

Correct myths about genetic disorders, and teach patients about the nature of genetic testing. In addition, help patients find accurate and helpful resource materials or websites. Medical-surgical nurses are not genetics experts and would not be expected to be the final source of definitive information; however, they can help ensure that the patient is referred to the correct level of genetic counseling. If you are present during the patient’s discussions with a genetics professional, assess whether the patient understands the issues regarding his or her health problem.

Patient Advocacy and Support

Ensure that the patient’s rights are not neglected or ignored. Ask the patient privately what his or her wishes are regarding genetic testing. Ask whether another person or agency is insisting on the testing. Remind the patient that he or she does not have to agree to be tested. Verify that he or she has signed an informed consent statement for the test.

Considering or having genetic testing is a stressful experience. The patient and family require strong support and may need help to find the best way to cope. Genetic testing should be performed only after genetic counseling has occurred and should be followed with an opportunity for more counseling.

Patients may feel anger, depression, guilt, or hopelessness. Patients who have positive results (results that indicate a specific mutation is present) from genetic testing may have issues of role changes, risk for early death or disability, and the possibility of having passed the risk for a health problem on to their children. Patients who have an ambiguous test result or one of unknown significance may feel that they have agonized over a decision, spent money, and still have no clear answer or direction. Even patients who have negative genetic test results (results that indicate a specific gene mutation is not present) need counseling and support. Some patients may have an unrealistic view of what a negative result means for their general health. Others may feel guilty that they were “spared” when other family members were not.

Assess the patient’s response to genetic test results. Ask about how he or she may have used coping mechanisms in the past. If the patient has disclosed information to family members, assess whether they can help provide patient support or need support themselves. Assess whether the information about positive test results has strained family relationships. Refer the patient to appropriate support groups and general counseling services.

For some positive genetic test results, such as having a *BRCA1* gene mutation, the risk for developing breast cancer

is high but is not a certainty. Because the risk is high, the patient should have a plan for prevention and risk reduction. One form of prevention is early detection. Thus a patient who tests positive for a *BRCA1* mutation should have at least yearly mammograms and ovarian ultrasounds to detect cancer at an early stage when it is more easily cured. Teach the patient who has positive test results that indicate an increased risk for a specific health problem about the types of screening procedures that are available and how often screening should occur. For example, some patients at known high genetic risk for breast cancer and ovarian cancer choose the primary prevention methods of bilateral prophylactic mastectomies (surgical removal of the breasts) and oophorectomies (surgical removal of the ovaries). Although these strategies are severe, they are effective and the patient should be informed about their availability.

In addition to increased screening, teach patients at known high genetic risk for a specific disorder how to modify the environment to reduce risk. For example, a patient who has a specific mutation in the *α1AT* (alpha₁-antitrypsin) gene is at increased risk for early-onset emphysema. The onset of emphysema is even earlier when the patient smokes or is chronically exposed to inhalation irritants. By modifying his or her environment, the disease can be delayed or the symptoms reduced.

GET READY FOR THE NCLEX® EXAMINATION!

KEY POINTS

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Determine whether an informed consent statement was obtained before any genetic test is performed.
- Keep all patient and family information regarding genetic testing confidential.

Health Promotion and Maintenance

- Identify patients and families at increased genetic risk for disease or disorder.
- Teach patients and families at known increased risk for disease or disorder what types of screening procedures and schedules are most appropriate (check specific disorder chapters for the appropriate screening guidelines).
- Teach patients and families at known increased risk for disease or disorder what types of environmental modifications can reduce risk, delay disease onset, or reduce symptom severity (check specific disorder chapters for appropriate modifications).

Psychosocial Integrity

- Assess patients who have received results of genetic testing for responses such as anger, guilt, or depression.

- Allow the patient and family who have been identified as being at increased genetic risk for serious health problems to express concerns and feelings.
- Ensure that the patient who undergoes genetic testing is appropriately counseled before testing, while waiting for test results, and after test results are obtained.

Physiological Integrity

- DNA, genes, and chromosomes are different forms of the same substance.
- All human cells with a nucleus contain all the genes.
- Every time a cell divides, it must replicate its DNA.
- The normal human chromosome number is 46.
- The purpose of a gene is to serve as the instructions for making a specific protein.
- Mutations can change the activity of a protein and have adverse effects on health.
- Many common adult diseases or disorders have a genetic basis (hypertension, diabetes, cancer) although some of these diseases also may occur among people with no genetic risk.
- Having a gene for a disorder does not necessarily mean that the disorder will ever develop.
- Genetic testing reveals information about the patient and his or her family members.

Evidence-Based Practice in Medical-Surgical Nursing

Answer Key for NCLEX Examination Challenges and
Decision-Making Challenges
Audio Glossary

Key Points
Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

1. Define evidence-based practice (EBP).
2. Describe the process of how best current evidence is used to make clinical decisions.
3. Explain how to use an EBP approach to identifying a clinical problem, issue, or challenge.
4. Formulate a focused clinical question about clinical practice.
5. List the steps of how to perform a systematic literature review to answer clinical questions.
6. Briefly describe two models of EBP.
7. Explain the steps of the evidence-based practice improvement (EBPI) model.
8. Discuss how the EBPI model can be used to guide a clinical practice improvement project.

OVERVIEW

All health care professionals need to understand and use an evidence-based practice (EBP) approach to practice. In 2003, the Institute of Medicine (IOM) published a report entitled *Health Professions Education: A Bridge to Quality*. That report contained the following mandate: “All health professionals should be educated to deliver patient-centered care as members of an interdisciplinary team, emphasizing evidence-based practice, quality improvement approaches and informatics” (p. 3).

In 2010, the IOM in partnership with the Robert Wood Johnson Foundation published *The Future of Nursing: Leading Change, Advancing Health* (Institute of Medicine, 2010). Among the four major recommendations is “Nurses should be full partners, with physicians and other health care professionals, in redesigning health care in the United States” (p. 3). The specifics of this recommendation include the need for nurses to be prepared to be full partners in health care improvement efforts. Aspects of this role include “taking responsibility for identifying problems and areas of system waste, devising and developing improvement plans, [and] tracking improvement over time ...” (p. 3).

Definitions of Evidence-Based Practice

According to several nursing experts and the Quality and Safety Education for Nurses (QSEN), EBP incorporates the best current evidence with the expertise of the clinician and the patient’s values and preferences to make a decision about health care (Levin & Lane, 2006; Melnyk & Fineout-Overholt, 2011). This definition was based on the work of Sackett et al. (2000), who had proposed three components of EBP—best evidence, clinical expertise, and patient values and preferences—as part of the definition of evidence-based medicine.

Ervin (2002) proposed this definition of EBP for nursing: “Evidence-based nursing practice is practice in which nurses make clinical decisions using the best available research and other evidence that is reflected in approved policies, procedures, and clinical guidelines in a particular healthcare agency” (p. 12). DiCenso et al. (2005) further extended this definition to include information about the patient’s clinical state and the setting or circumstances in which health care is being provided.

The EBP process is collaborative and involves all members of the health care team. This model is shared by many health

care professions and is not unique to nursing. Therefore, although other professions might refer to the model as evidence-based medicine (EBM) or evidence-based social work similar to how DiCenso et al. (2005) specified the practice of nursing, the authors of this text refer to the model as EBP.

Steps of the Evidence-Based Practice Process

The process of EBP is systematic and includes several steps as presented by Sackett et al. (2000) in the context of practicing and teaching medicine.

1. Asking “burning” clinical questions
2. Finding the very best evidence to try to answer those questions
3. Critically appraising and synthesizing the relevant evidence
4. Making recommendations for practice improvement
5. Implementing accepted recommendations
6. Evaluating outcomes

Asking “Burning” Clinical Questions

Clinical questions are derived when clinicians do not have all the information they need to make the best possible decisions about patient care. A “burning” clinical question is one that usually arises in daily practice or when attending a class or reading a professional journal. The question may arise in relation to an individual patient, a group or population of patients, or a patient care unit or larger organizational area. An example of an *individual* patient question that a nurse might ask is, My older hospitalized patient who has been placed on fall precautions fell in the bathroom. What else could I have done to prevent this patient from falling, and what can I do to prevent her from falling in the future? At a *group or population* level, the nurse might ask, What are current best practices for assessing in the hospital patients’ risk for falls, and/or what are best practices for fall prevention in patients who are at risk for falls? At a *unit or organizational* level, the question might be, Is the current policy and procedure for assessing patients’ risk for falls and for implementing preventive practices based on the best available evidence?

Once you critically think about and pose a question about clinical practice, you will need to find out at what level the question needs to be answered (i.e., at the individual patient level, patient population level, or organizational level). If the latter two levels are where the problem exists, then begin to gather background information from the literature and internal evidence from your organization to describe the problem more fully (Levin et al., 2010).

One way you can begin to use EBP in your practice is to review the policy and procedure for a specific nursing practice in your clinical setting and determine what type of evidence was used as the basis for that policy and procedure. Does the protocol list references? What types of references are cited?

Once you have described the clinical practice problem and can focus on exactly what concerns you have, ask yourself whether the question is a *background* or a *foreground* question. A *background* question usually asks for a fact, a statement on which most authorities or experts would agree. For example, What is the etiology of congestive heart failure? What are the most frequently prescribed analgesics for the management of postoperative pain? The answers to these

types of questions can usually be found in a textbook and are not controversial. A *foreground* question, on the other hand, usually asks a question of relationship and may be controversial. An example of this type of question is, What are the most effective interventions for treating venous leg ulcers?

Qualitative Versus Quantitative Questions. If you are asking a foreground question, develop a more specific, detailed clinical question to guide your search for evidence. The two types of clinical questions are qualitative and quantitative. A **qualitative question** focuses on the meanings and interpretations of human phenomena or experience of people and usually analyzes the content of what a person says during an interview or what a researcher observes. Examples of qualitative questions are:

- What is the experience of having cancer like for young adults?
- How do older women respond to a residential move to assisted-living facilities?
- What are the differences in nurses’ work culture between acute care and home care agencies?

A **quantitative question** asks about the relationship between or among defined, measurable phenomena and includes statistical analysis of information that is collected to answer a question. Examples of quantitative questions are:

- What is the effect of using a new assessment tool to predict the likelihood of falling to frequency and severity of falls in patients undergoing hip replacement?
- What is the effect of hydrocolloid dressings compared with silver-impregnated dressings on the rate of wound healing in patients with postsurgical incision wounds?

PICO(T) Format. Nursing authors suggest framing clinical questions in a PICO (Cullum et al., 2008; Levin & Lane, 2006) or PICO(T) format. The PICO(T) format is outlined in [Table 7-1](#). The major components of a focused clinical question are the **population**, **intervention**, **comparison**, and **outcome**, with an added **time** component when appropriate.

The *population* indicates the specific group of patients to whom the question applies. This component is important because evidence that may support an intervention with one group of patients may not apply to another group of patients. For example, a fall prevention program for older adults who live at home may be very different from a fall prevention program for patients who attend a rehabilitation program. Be sure to think about the age, gender, ethnicity/race, and disorder to narrow your population of interest.

The *intervention* component pertains to the therapeutic effectiveness of a new treatment and may include (1) exposure to disease or harm, (2) a prognostic factor, or (3) a risk behavior or factor (e.g., the need for toileting to help prevent falls) (Melnik & Fineout-Overholt, 2005). For example, one might compare a group of smokers to a group of nonsmokers to determine the relationship of smoking to bladder cancer.

The *comparison* component of the clinical question may be either the standard or current treatment or may be another intervention with which the innovative practice is compared. In the case of prognostic questions, the comparison may consider another factor or potential influence that could affect the outcome of the patient’s health. A preventive question might examine the absence of the risk factor as the comparison; for example, the need for toileting compared with no need for toileting to prevent falls.

TABLE 7-1 EXAMPLES OF COMPONENTS OF PICO(T) QUESTIONS IN RELATION TO TYPE OF QUESTION

	THERAPY	ETIOLOGY	DIAGNOSIS	PREVENTION	PROGNOSIS	MEANING
Population						
Intervention						
Comparison						
Outcome						
Time						

The *outcome* component specifies the measurable and desired outcomes of your practice innovation, diagnosis, or prevention intervention. Outcomes may include measures of the results of an intervention (e.g., patients' perception of pain, number of days spent in a hospital, or need for rehabilitative services). Or your outcome might focus on the sensitivity and specificity of a diagnostic test or nursing assessment tool (e.g., what is the best tool for assessing the risk for patient falls on an orthopedic unit?).

Fineout-Overholt and Stillwell (2011) advocated adding a *time* component or time frame to the focused clinical question. The question may include specifying within what time period one would expect the outcome(s) to occur. An example of a completed PICO(T) question is, What is the effect of adding hourly rounding to the standard falls protocol for the geriatric unit (patients 65 years or older) in hospital Y on the process of care provision (to be more specifically defined) and the outcomes of rate of falls, fall morbidity, and clinician satisfaction within a 3-month period?

Arriving at the focused clinical question is not an easy task, even for seasoned clinicians. Defining the specific question requires these three steps—identifying the problem, clarifying the problem, and focusing the question (Levin & Lane, 2006).

Finding the Best Evidence

Finding the best available evidence to answer a focused clinical question has been a challenge for clinicians and health care agencies. The major barrier that prevents nurses from engaging in evidence-based practice is lack of time. Other barriers include:

- Lack of value for research in practice
- Lack of understanding of organization or structure of electronic databases
- Difficulty accessing research materials
- Lack of computer skills
- Difficulty understanding research articles.

The health care system is addressing these challenges in many settings to improve the safety and quality of patient care. Many hospitals and community health care agencies are involved in promoting evidence-based practices and projects to reach national safety goals. An example of how staff nurses are essential contributors and collaborators on such projects is presented at the end of this chapter in the "Application of the EBPI Model to Clinical Practice" section.

Levels of evidence refers to the status or rank of evidence. Most evidence hierarchies are pyramids with the highest level of evidence at the top (Fig. 7-1). The type of evidence needed depends on the nature of the clinical question—Is the question quantitative or qualitative? For example, if you are asking about the effectiveness of different types of compression

FIG. 7-1 Pyramid of evidence for questions of therapy. CPGs, Clinical practice guidelines; RCTs, randomized controlled trials.

bandages on healing of venous leg ulcers, you would want to *measure* the change in size of the ulcer as one indication of healing (*quantitative*). On the other hand, you might be interested in what the experience of having a chronic venous ulcer is like for women (*qualitative*). Each type of question requires different types and sources of evidence to find an answer. Table 7-2 provides an internationally accepted hierarchy for qualitative levels of evidence.

A preliminary evidence search entails identifying whether quality clinical practice guidelines (CPGs) exist to answer the clinical question. A **clinical practice guideline** is an "official recommendation" based on evidence to diagnose and/or manage a health problem (e.g., pain management). If these guidelines are of high quality and they contain the answer to your question, the search may be complete (Levin et al., 2007).

If the guidelines do not provide a sufficient answer to your question and/or they are not based on high quality evidence, you need to search the "Fantastic Four" databases:

- Cochrane Library of Systematic Reviews
- Joanna Briggs Institute (JBI) systematic reviews

- Medline (or PubMed)
- Cumulative Index to Nursing and Allied Health Literature (CINAHL)

Other databases may also contain a wealth of information depending on the nature of the question. For example, if you are asking a psychological question about the best way to help patients deal with anxiety, then PsycINFO would be a good source. The instructional or health sciences librarian at the local college/university or clinical agency can assist in finding the best current evidence to answer your question. In some cases, you may need to revise the search if the original terms used did not access relevant citations. Table 7-3 provides a template that you can use for any evidence search that you undertake.

If a continued literature search is needed for *quantitative* clinical questions, start with looking for the top level of evidence (i.e., systematic reviews, clinical practice guidelines based on top level evidence, and/or randomized or multi-site clinical trials) (see Fig. 7-1). If searching for answers to *qualitative* questions, look first for meta-analyses or meta-syntheses. The major purpose of providing systematic reviews of evidence on a topic is so that busy clinicians will not have to spend many hours finding original single studies and then reviewing, critiquing, and synthesizing each study's evidence. In some cases, evidence summaries are available (Table 7-4). Fig. 7-2 provides a guide for conducting a systematic evidence search.

Critically Appraising and Synthesizing Evidence

The key to this step is a collaborative team effort. One effective strategy is to have each member of an EBP team take responsibility for summarizing and critically appraising a select number of articles (depending, of course, on the

FIG. 7-2 Algorithm for systematic review of the published evidence. CINAHL, Cumulative Index to Nursing and Allied Health Literature.

TABLE 7-2 JBI LEVELS OF QUALITATIVE EVIDENCE FOR MEANINGFULNESS*

LEVEL OF EVIDENCE	MEANINGFULNESS M (1-4)
1	Meta-synthesis of research with unequivocal synthesized findings
2	Meta-synthesis of research with credible synthesized findings
3	a. Meta-synthesis of text/opinion with credible synthesized findings b. One or more single research studies of high quality
4	Expert opinion

number of relevant articles your search revealed) and then presenting the review to all team members. This helps clarify, extend, and come to consensus on what the best evidence is to answer the clinical question.

Making Recommendations to Improve Practice

Once you have reviewed and critically appraised all the relevant evidence, you are ready to make practice recommendations in a written report to whoever needs to review them for potential approval. The clinical application at the end of the chapter illustrates this process.

Implementing Recommendations

This step is perhaps the most exciting and energizing component of an EBP project. After all the hard work of focusing the practice problem, critically appraising the evidence, and getting practice recommendations approved, the protocol and implementation plan can be developed. This plan should improve practice, patient outcomes, and the desired outcomes of the system (e.g., cost savings). Approaches to implementation are varied. Examples of models to guide EBP projects are presented in the next section of this chapter.

Keep in mind that the process of implementation needs to be systematic, shared, and consistent. That is, the implementation protocol has to be followed strictly so that any outcomes that are achieved are actually based on the new EBP innovation being implemented. Therefore complete buy-in from the people who will be involved in implementing the new practice is essential.

DECISION-MAKING CHALLENGE

Evidence-Based Practice; Quality Improvement; Safety

An 82-year-old alert and oriented woman was admitted with a diagnosis of congestive heart failure. She also has urinary frequency. You notice on her chart that she is a “high falls risk.” Over 70% of patients on your unit are also at high risk for falls. The written policy and procedure for fall prevention at your hospital states that patients at risk for falling should have:

- Their health care record flagged with a green star
- A green star placed on their room or bed
- A bed alarm installed
- Their siderails up at all times, except when a visitor, nurse, or nursing assistant is present

The patient felt the urge to urinate and pressed her call light. Someone on the intercom told her that she would assist her shortly. After 15 minutes, the patient had to make a decision to either urinate in bed or climb over the siderails to go to the bathroom. She decided to climb over the siderails and fell. The bed alarm went off after she left the bed.

1. Considering that over 70% of patients admitted to your unit are flagged as “at risk for falls,” how do you think the nurses decide that a patient is at risk for falling? Are they using valid, reliable, sensitive, and specific assessment tools to make this determination?
2. In a population of inpatient older adults, what factors can predict patient falls with a high degree of accuracy?
3. Does the best available evidence support the use of bed alarms as an intervention that prevents falls in inpatient adults of any age?
4. In a population of adult inpatients, what are the factors that have been shown by research to be the most predictive of falls?
5. What interventions have been shown to decrease the fall rates in acute care institutions with this population?

Evaluating Outcomes

Evaluating outcomes requires valid and reliable measurement tools. For example, if the clinical question is evaluating the effect of music therapy on reducing postoperative abdominal pain, then a tool to measure pain intensity and quality would be used. Many of these tools are cited in the literature and can be used without permission. Others require that permission be obtained in writing. Be sure to determine whether permission is needed before you use any measurement tool.

MODELS AND FRAMEWORKS FOR IMPLEMENTING EVIDENCE-BASED PRACTICE

Several authors have attempted to develop models or conceptual frameworks to facilitate an understanding of the complex process of introducing evidence-based improvement efforts (Rycroft-Malone & Bucknall, 2010). Each model highlights factors or processes that need to be considered when attempting to implement practice change.

Iowa Model

The major purpose of the Iowa model of EBP is to help health care professionals use evidence to improve patient outcomes. Originally developed as a model for research utilization, Titler revised and enhanced the model in 2010 to incorporate the elements of EBP. Important aspects of the current model include the (Titler, 2010):

- Triggers that lead to clinical questions
- Assessment of whether these questions are priorities for the health care organization
- Focus on forming a team to develop an EBP initiative
- General overview or steps for deciding about whether to implement and then adopt a change in practice

Reavy and Tavernier Model

Reavy and Tavernier (2008) developed a model and process to implement EBP that uses concepts from previously developed models (e.g., Stetler model, Iowa model) and builds upon them. The emphasis of the Reavy and Tavernier model is on the crucial role of the direct caregiver (e.g., the staff nurse) in making changes to enhance clinical practice. The authors of the model view the staff nurse as the clinical expert and believe that the expertise of a nurse researcher is needed to facilitate the EBP process by serving as a teacher, role model, and support nursing staff in identifying areas for improvement, assisting staff with literature reviews and synthesis of evidence, and helping with the implementation and evaluation of EBP projects. Reavy and Tavernier suggest that if a nurse researcher is not available in the practice setting, then a clinical nurse specialist, advanced practice nurse, or nurse manager might provide the needed support to staff nurses. Also included in this model is an emphasis on patient preferences and values, yet there is little explanation of the crucial role of patient as stakeholder in any practice improvement efforts. See Table 7-5 for a more detailed description of this model.

ARCC Model

The Advancing Research and Clinical Practice through Close Collaboration (ARCC) model of evidence-based practice was

	PATIENT VALUES AND PREFERENCES	STAFF NURSE/CLINICAL EXPERT	NURSE RESEARCHER/BEST AVAILABLE EVIDENCE
Assessment	Give verbal and nonverbal communication	Receive verbal and nonverbal messages (collect data)	
Identification and evaluation of problem		1. Identify problem(s) 2. Discuss potential interventions and outcome 3. Conduct literature search	Assist with literature search as needed
Analysis and synthesis of best available evidence		1. Analyze and critique best available evidence 2. Synthesize evidence	Assist with analysis and critique as needed
Planning		1. Assess feasibility of change 2. Define proposed change 3. Identify resources 4. Define desired outcome	
Implementation and evaluation	Receive nursing care based on best evidence	1. Design and implement peer teaching strategies 2. Implement change 3. Conduct pilot study 4. Evaluate findings 5. Decide to adopt or reject change 6. Communicate findings	1. Provide assistance with pilot study 2. Receive communication related to ideas for research
Integration and maintenance	Receive nursing care based on best evidence	1. Integrate into policies 2. Monitor process 3. Monitor outcomes 4. Communicate updates	Receive communication related to ideas for research

Data from Reavy, K., & Tavernier, S. (2008). Nurses reclaiming ownership of their practice: Implementation of an evidence-based practice model and process. *Journal of Continuing Education in Nursing*, 39(4), 166-172.

originally developed by Bernadette Melnyk in 1999 and has been enhanced by Melnyk and Fineout-Overholt over the past 10 years (Melnik & Fineout-Overholt, 2010). The current version of the model consists of several components and how they relate to each other. The major components of the model are:

- Organizational assessment and readiness to implement EBP
- Identification of strengths and barriers to EBP implementation
- Development and use of EBP mentors
- Implementation of EBP
- Measurement of nurse, system, and patient outcomes

Key to this model is the development and use of EBP mentors who teach, guide, and facilitate agency staff in the implementation and evaluation of evidence-based practices (Melnik & Fineout-Overholt, 2010).

EVIDENCE-BASED PRACTICE IMPROVEMENT (EBPI) MODEL

Steps of the EBPI Model

The EBPI model developed by Levin et al. from the Visiting Nurse Service of New York (Levin et al., 2010) combines the best of the EBP and PI/QI (process/quality improvement) systems into one approach for implementing practice improvement. The model is prescriptive and easy for guiding health care practitioners from any discipline and setting to achieve positive change. As depicted in Fig. 7-3, the model includes:

- The description of the practice problem
- The formulation of a focused clinical question (in PICO format)
- The search for evidence to answer the question
- The appraisal and synthesis of relevant evidence
- The development of an aim statement or project goal
- The development, implementation, and evaluation of the protocol for practice improvement
- The use of small tests of change or plan, do, study, act (PDSA) cycles to test methods
- The dissemination of best practices

Adopted from the process improvement approach is the idea of PDSA cycles or small tests of change (Langley et al., 2009). Many professionals in health care, business, and other fields implement what they believe is a good idea for an improvement on too-large a scale before they have perfected the new practice or even assessed how successful it may or may not be in their setting with their populations (patients or consumers). One of the most important benefits of small tests of change is that you have a chance to perfect the process or practice that you want to implement before disseminating and using the practice on a wide scale. Small tests of change for EBPI projects in health care are conducted with a small group of people (e.g., patients or staff) for a short period and may be repeated several times until the implementation protocol is perfected (Levin, 2009).

During small tests of change, it is helpful to use the concept of **PDSA** cycles to guide the activities.

- “P” stands for “plan” and is the first step in introducing a practice change. During this phase, a project team develops a protocol for implementation, which includes

FIG. 7-3 The EBPI model.

not only the protocol or procedure for the practice innovation but also a total plan for the exact process that will be followed for implementing the project. It includes who will be administering the new practice, how it will be implemented, the time frame for implementation, and how the particular processes implemented for each small test of change will be evaluated.

- “D” stands for “do” and is the action-oriented phase of the process. The new innovation or a portion of it is tested according to the plan.
- “S” stands for “study” and refers to the review and analysis of data collected during the “do” phase of the cycle.
- “A” is the “analysis” and evaluation of results from the small test to guide decisions about how to proceed.

Decisions then need to be made about how to revise or refine the practice protocol and institute another small test of change to try out the refined protocol and/or whether the plan is worth continuing.

Application of the EBPI Model to Clinical Practice: A Case Study

Describe the Practice Problem

On an adult general surgical unit in a community hospital, the nursing staff identified that assessing patients’

postoperative pain with the current practice of using a numeric 10-point rating scale did not seem to be an effective assessment tool when the patient was lying quietly or appeared to be asleep. The nurses thought that to ask the restful patient to scale his or her pain refocused the patient on the pain and was not supportive of patient relaxation and pain relief. When this type of clinical observational pain assessment was performed, the nurse often did not chart the assessment in the medical record: How could the nurse label the level of pain on the scale when patient behaviors were used to assess pain? To document pain assessment and management in the patient’s health record, the nurse would make up a pain rating score. A nurse’s note could have been added to the medical record to describe pain behaviors the nurse identified as indicators that pain appeared to be decreasing and pain medication was working. However, the nurses on the unit did not write notes until the end of the shift. Thus the health record appeared as if no re-assessment had taken place and that the nurses were not following hospital policy.

The nurses on the unit identified that pain assessment needed to be improved for quality patient care. A small team of staff nurses who understand the EBP process was formed to lead the project to address the clinical concerns. The staff identified that the main focus of the problem was assessment of patients who were asleep or appeared asleep. Was there a reliable and valid method to assess pain by observing behaviors without disturbing the patient? The nurses identified that the numeric rating scale worked for most postoperative patients after the second postoperative day. The clinical concern was assessing and re-evaluating pain management within the first 24 hours after surgery when patients were tired and often asleep because of the remnants of anesthetic and being heavily medicated for pain.

A chart audit confirmed that the nursing staff consistently assessed and re-evaluated pain with the numeric rating scale on the second postoperative day. Pain was assessed according to standards 95% of the time. On the first day after surgery, the pain scale was documented only 12% of the time. Nurses’ notes to describe the patients’ pain were written only 60% of the time during the first postoperative day. Clearly, there was a problem documenting pain assessment on the first postoperative day.

No one doubted that the nurses assessed pain frequently and provided pain relief; however, only the administration of pain medication was documented. Pain assessments were not consistently charted and, from a legal standpoint, the pain assessment was not done. When the numeric pain scale was used, the nurses consistently met hospital standards for pain assessment and evaluation of pain relief. The chart audit showed that a new, easy-to-use tool that assessed pain behaviors was needed to improve the documentation of pain assessment.

Formulate a Focused Clinical Question

After conducting the chart audit, the EBP team defined the clinical problem and framed a PICO question to focus the literature search for evidence-based strategies to improve pain assessment. The PICO question developed was, In the adult hospitalized patient (P), does the implementation of a behavioral pain scale (I) compared with the use of a visual analog scale (C) improve the assessment and management of pain in patients on the first postoperative day (O)?

Search for Evidence

The EBP team went to the hospital library and accessed the CINAHL database. The initial search term used was “Pain Assessment.” This search provided 2934 article results for the years 1971 to 2010 (www.EBSCOHOST.com, retrieved August 30, 2010). No matter how many nurses worked on the project, it would be impossible to read and evaluate over 2000 articles. The team then remembered to use the PICO template as a guide to focus the search. Limits to narrow the search were added to request only articles for pain assessment or measurement in adults ages 19 years and older. Just limiting the articles by the age of the patient reduced the number of articles to 586 (www.EBSCOHOST.com, retrieved August 30, 2010). This was a more manageable number of articles but still a huge number to review from a practical standpoint. Articles from 2010 appeared on the first page of the search screen. The titles revealed many interesting yet varied article topics. The search retrieved articles that addressed pain assessment with culture and pain assessment methods for specific medical diagnoses. Yet articles that specifically addressed behavioral pain assessment tools were not immediately apparent in a list of 586 articles.

The team realized that using the PICO question keywords might help narrow the search to the specific topic of interest and to a manageable number of articles to review. Using the search options of “postoperative pain” and “clinical assessment tools,” the search engine revealed 117 articles for review (www.EBSCOHOST.com, retrieved August 30, 2010). The nurses then saved the complete search so that they could refer to the list and read other articles as they explored solutions to the PICO question.

The EBP team reviewed the search results and identified five articles that appeared to address the clinical question specifically. One article discussed the use of three evidence-based practices for postoperative pain assessment (Carlson, 2009). The nurses were intrigued by the title of this article—is it possible that the authors have already evaluated three different methods that address their specific clinical question and that it can be read in one article? Another article examined abdominal surgery patients’ pain management from the postanesthesia care unit (PACU) to the surgical unit (Wilding et al., 2009). Since PACU-to-unit transition takes place during the early postoperative period, the time that pain assessment using current practice is a concern, this article seemed to address the PICO question. The third article identified behavioral pain indicators of postoperative pain with delirium (Decker, 2009).

Although the nurses did not specifically identify delirium as a concern, perhaps the behavioral pain tool discussed in the article could be applicable to other populations of patients besides those with delirium. The fourth article focused on pain assessment tools in the critical care unit (Hall, 2007). This article evaluated three pain assessment tools. Thus the nurses chose to review this article to see if any of the tools discussed could be used on the general surgical floor. Finally, the nurses chose to review an article discussing the Checklist of Nonverbal Pain Indicators (CNPI) (Feldt, 2000) because this tool repeatedly appeared in the literature search. Even though the CNPI was developed to assess pain in cognitively impaired adults, the nurses thought that because many patients on the postoperative unit are older, the tool might be promising.

Appraise and Synthesize the Evidence

The team read the articles and completed tables of evidence (TOEs) so the information from the articles could be organized and discussed. The TOEs also helped the nurses systematically organize what they read in a consistent format for group discussion and analysis (Table 7-6). These tables were used as the group discussed their individual review of the articles, which included a summary of the evidence contained in the article, the strengths and limitations of the evidence, and potential application to their specific PICO question. As the nurses critically appraised the evidence, the group referred to the quantitative evidence pyramid in Fig. 7-1 to identify the level of evidence of each article. The colorful pyramid was posted during the discussion for ease of reference. Through dialog about each article, the authors’ methods, outcomes, and the limitations of the different tools to measure pain, the group rated the quality of the articles. This process was used to make an informed decision about the strength of the evidence before any practice recommendations could be made. The staff wanted to use the highest level of evidence possible to inform the practice change. The critical care article was identified as a level III quasi-experimental study and presented a description of a tool that was reported as “easy to use” and reliable for nonverbal patients (Hall, 2007). The staff returned to the literature search to find more information on one of the behavioral pain tools discussed in the same article.

Develop the Aim Statement

After reviewing the evidence to answer the focused clinical question, the nurses developed the following aim statement: Improve the frequency of nurses’ assessment of first-day postoperative pain from 12% to 70% after 2 weeks of introducing a new behavioral pain assessment tool.

Implement the PDSA Cycles

After the second search for evidence to answer the clinical question and additional review of the new evidence, the team of nurses **planned** to make a practice change. A small test of the utility of the tool needed to be performed to see if the nurses could accurately assess pain using the behavioral assessment tool and to determine its practicality for use. To evaluate the inter-rater reliability of the tool to determine if the nurses could consistently assess a patient’s pain in the same way with the same tool, three of the nurses used the tool simultaneously to assess pain in 10 postoperative patients (**Do**). The assessment results were compared and evaluated to identify whether the nurses were using the tool consistently (**Study**). This small test of change resulted in positive feedback from nurses as to the practicality of the tool, and inter-rater reliability was high (i.e., different nurses observing patients and assessing their pain at the same time using the new tool came up with consistently similar ratings of these patients’ pain).

The next step was to perform another small test of change (**Act**) to evaluate if nurses on the EBP team could use the pain assessment tool effectively in the clinical unit to improve patient pain assessment. The team used the tool for 1 week on all first-day postoperative patients. Patient records were monitored daily by the nurse educator and unit manager to evaluate the frequency of pain assessment. Because the team had the initial chart audit data, collecting the same data with

Feldt, K. (2000). The Checklist of Nonverbal Pain Indicators (CNPI). <i>Pain Management Nursing</i> , 1(1), 13-21.	88 Patients with surgical repair of hip fracture on third postoperative day 88% Women with a mean age of 83.2 yrs	Prospective comparison to determine if there were differences in observed pain behaviors between cognitively impaired and non-cognitively impaired adults. This is a test of validity of the CNPI instrument. Level III: quasi-experimental design	Patients' pain assessed using the Ferrell Pain Experience Interview, Visual Distress Survey, and the CNPI. Also, cognitive status assessed with the Mini-Mental State Examination. The CNPI was used to assess pain and compare the results with the other tools and compare the results between cognitively and non-cognitively impaired patients.	Initial CNPI instrument testing: good face validity; 93% inter-rater reliability; Kappa statistic was 0.625 to 0.819 ($p = .019$ to $.0057$). The cognitively and non-cognitively impaired groups' CNPI scores did not differ significantly in total scores. The cognitively impaired group had more pain behaviors identified at rest than the non-cognitively impaired group.	This was an initial test of the CNPI in cognitively impaired older adults. It seems to be reliable and simple to use. The CNPI seems to be most effective in non-cognitively impaired patients with more nursing assessment needed to follow up on assessment of patients at rest.

the new tool in use would help identify if the behavioral scale for assessment of pain was completed and documented more consistently than before the new scale was introduced. In addition, the EBP nurse team was able to develop a step-by-step process for use of the tool.

The next step in the EBPI implementation process was for the project team to educate the rest of the unit staff on all shifts about the evidence-based intervention—the behavioral pain assessment tool and the process for its use. The TOEs were summarized and discussed to provide the staff with concrete information about the new tool. The EBP nurse team demonstrated how the tool was used. A member of the project team pretended to be asleep in a bed as a patient so that the nurses could role-play how to perform the pain assessment with the proposed tool. Informational posters were placed on the unit and multiple copies were made of the tool for use during the small test of change. The unit secretaries were involved in the education since they were responsible for providing the tools and collecting them when they were completed.

For 2 weeks, the nursing staff used the new tool to assess the pain of first-day postoperative patients. The team reviewed patient charts daily and answered questions about the use of the tool and the documentation of the pain assessment. At the completion of this third small test of change, the team reviewed the chart audits and found that the unit nurses had appropriately documented pain assessment on the first postoperative day 85% of the time—a huge improvement! A short

questionnaire was distributed to the nursing staff to determine their feedback about the use and effectiveness of the tool. All unit staff found the new tool easy to use and expressed positive beliefs in its value. They also were very proud to have achieved an outcome that exceeded their outcome in the aim statement.

Disseminate Best Practices

Given the success the nurses achieved on this one postoperative unit with their small tests of change using PDSA cycles, they recommended the introduction of the new behavioral pain assessment tool to the Hospital Standards of Practice Committee. The Committee, consisting of a multidisciplinary team of nurses, physicians, pharmacists, and other health care professionals, was excited about the evidence-based practice improvement effort. They decided to pilot the new tool on all surgical units for 1 month to see if the same results could be achieved with wider dissemination. If the initial benchmark of 70% was achieved in the pilot, then the new protocol for assessment of pain on the first postoperative day would be instituted hospital-wide as the standard of practice. At completion of the pilot, the benchmark of 70% was achieved and the Committee voted to incorporate the new policy and procedure as standard practice.

All nurses who worked on surgical units, the operating suites, and PACU were educated about the new hospital standards for pain assessment. The plan for evaluation of the new practice was to conduct random patient record audits each

month for 6 months to determine whether the improvement effort continued after 6 months. The nurse educator and the EBP mentor worked with the initial EBP nurse team (three staff nurses) to submit an abstract for presentation at

an EBP conference. The Vice President of Patient Care Services agreed to pay all expenses for the five nurses who led the project to attend the conference if the abstract was accepted for presentation.

KEY POINTS

Review these Key Points.

- Evidence-based practice (EBP) is a strategy for making clinical decisions about how we practice nursing and other health care professions.
- EBP incorporates the expertise of the clinician and the patient's values and preferences to make decisions about health care.
- The first step of the EBP process is to ask a clinical "burning" question using the PICO(T) format (see [Table 7-1](#)).
- Quantitative questions focus on the relationship among measurable phenomena and include statistical analysis of information.
- Qualitative questions focus on the meanings and interpretations of human phenomena or experiences of people using interview or observation.
- Levels of evidence refer to the status or rank of evidence (as shown in [Fig. 7-1](#) and [Table 7-2](#)).
- Examples of models of EBP include the Iowa model, Reavy and Tavernier model (see [Table 7-5](#)), and the evidence-based practice improvement (EBPI) model.
- When performing a literature search on current evidence to answer the clinical question, organize the data into a table of evidence like the one shown in [Table 7-6](#).
- When making changes based on findings from the literature, use PDSA cycles to test the changes on a small scale. PDSA stands for "Plan," "Do," "Study," and "Analyze."

Rehabilitation Concepts for Chronic and Disabling Health Problems

Answer Key for NCLEX Examination Challenges and
Decision-Making Challenges
Audio Glossary

Key Points
Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Identify the roles of each member of the interdisciplinary rehabilitation team.
2. Explain the importance of collaborating with members of the rehabilitation team when providing patient care.
3. Delegate and supervise selected nursing tasks as part of care for the rehabilitation patient.
4. Coordinate recommendations for home modifications with the patient, family, occupational therapist, and case manager.
5. Use safe patient handling practices based on current evidence to prevent self-injury.

Health Promotion and Maintenance

6. Develop a teaching plan to prevent complications for the rehabilitation patient who has impaired physical mobility.

Psychosocial Integrity

7. Assess the patient's response to chronic or disabling health problems.
8. Identify special considerations for older adults undergoing rehabilitative care.

Physiological Integrity

9. Interpret health assessment findings to plan appropriate collaborative care for the rehabilitation patient.
10. Assess the ability of patients to use assistive/adaptive devices to promote functional ability.
11. Plan interventions to prevent skin breakdown for rehabilitation patients.
12. Differentiate retraining methods for a patient with a spastic versus flaccid bladder and bowel.
13. Explain the primary concerns for patients being discharged to home after rehabilitation.

A **chronic health problem** is one that has existed for at least 3 months. A **disabling health problem** is any physical or mental health/behavioral health problem that can cause disability. This text focuses on physical health problems; mental health/behavioral health problems are discussed in textbooks on mental health/behavioral health nursing.

Patients with chronic and disabling health problems often participate in rehabilitation programs to prevent further disability, maintain functional ability, and restore as much function as possible. The rehabilitation nurse collaborates with the nursing and health care team and coordinates the patient's interdisciplinary care.

OVERVIEW

Chronic and disabling illnesses are a major health problem in the United States, with almost half of the population having one or more chronic health problems. Complications of chronic disease account for the majority of all deaths, and associated medical costs account for over two thirds of the nation's health care cost. The rate of chronic and disabling conditions is expected to increase as more "baby boomers" approach late adulthood. Some people with chronic and disabling problems are in inpatient settings like rehabilitation centers and skilled nursing facilities, whereas others are managed at home.

Stroke, coronary artery disease, cancer, chronic obstructive pulmonary disease (COPD), asthma, and arthritis are common chronic diseases that can result in varying degrees of disability. Most occur in people older than 65 years. Younger adults are also living longer with potentially disabling congenital or genetic disorders that, in the past, would have shortened life expectancy. These specific health problems are discussed throughout this text.

Chronic and disabling conditions are not always illnesses (e.g., heart disease); they may also result from accidents. Accidents are a leading cause of death among young and middle-aged adults. Increasing numbers of people survive accidents because of advances in medical technology and safety equipment such as motor vehicle air bags. As a result, they are often faced with chronic, disabling neurologic conditions, such as traumatic brain injuries (TBIs) and spinal cord injuries (SCIs).

These health problems are also common among military survivors who served in Iraq and Afghanistan. The most common complications of these wars are TBI and single or multiple limb amputations. These disabilities require months to years of follow-up health care after returning to the community. Because of people living longer with chronic and disabling health problems, the need for rehabilitation is on the rise.

A growing number of middle-aged and older adults have total joint replacements, most often hips and knees. Many of these patients need daily (5-day-a-week) rehabilitation in skilled or transitional care units, often within long-term care (LTC) settings such as nursing homes. Older adults generally do not want to be admitted to nursing homes. The nurse or case manager needs to explain that the nursing home stay will be short, ranging from 1 to 6 weeks depending on the patient.

Some facilities have dedicated units for patients having short-term rehabilitation. Others have devoted units to geriatric rehabilitation or ventilator weaning. Follow-up rehabilitation therapy three times a week can be continued at home or on an outpatient (ambulatory care) basis.

Concepts Related to Rehabilitation

Rehabilitation is the continuous process of learning to live with and manage chronic and disabling conditions, often those resulting from trauma. The main outcome of rehabilitation is that the patient will return to the best possible physical, mental, social, vocational, and economic capacity. Rehabilitation is not limited to the return of function in post-traumatic situations. It also includes education and therapy for any chronic illness characterized by a change in a body system function or body structure. Rehabilitation programs related to respiratory, cardiac, and musculoskeletal health problems are common examples that do not involve trauma.

After the acute condition or injury has been stabilized in a hospital, the patient may be discharged to continue the healing process at home, generally under the follow-up care of a nonhospital health care provider (e.g., a family physician). The nurse provides home care preparation, health teaching, psychosocial preparation, and information about various health care resources to help the patient resume his or her usual roles in society.

Some health problems require the intermediate step of rehabilitation (“rehab”), which can occur in a number of settings. Rehabilitation starts in the acute care hospital (sometimes called *acute rehabilitation*) and continues after discharge

from the hospital. The nurse coordinates care from acute care through community-based care to ensure successful rehabilitation.

For continuing rehabilitation services, the most common inpatient rehabilitation facilities (IRFs) are freestanding rehabilitation hospitals, rehabilitation or skilled units within hospitals (e.g., transitional care units [TCUs]), and skilled nursing facilities (SNFs) to which the patient is typically admitted for 1 to 3 weeks.

Ambulatory care rehabilitation departments and home rehabilitation programs may be needed for continuing less-intensive services. Some agencies have specialized clinics focused on rehabilitation of patients with specific health problems, such as those that care for patients with strokes; amputations; and large, chronic, and/or non-healing wounds. After disabled patients become more confident and independent, they may choose to live at home or in a group home. Group homes are facilities in which patients live independently together with other disabled adults. Each patient or group of patients has a care provider, such as a personal care aide, to assist with ADLs and decisions requiring accurate judgments. The patients may or may not be employed. The purpose of these centers is to provide independent living arrangements outside an institution, especially for younger patients with TBI or SCI.

The Rehabilitation Team

Successful rehabilitation depends on the coordinated effort of a group of the patient, family, and health care professionals in planning, implementing, and evaluating patient-centered care. The focus of the rehabilitation team is to restore and maintain the patient’s function to the extent possible.

In addition to the patient, family, and/or significant others, members of the interdisciplinary health care team in the rehabilitation setting may include:

- Physicians
- Nurses and nursing assistants
- Physical therapists and assistants
- Occupational therapists and assistants
- Speech-language pathologists and assistants
- Rehabilitation assistants/restorative aides
- Recreational or activity therapists
- Cognitive therapists or neuropsychologists
- Social workers
- Clinical psychologists
- Vocational counselors
- Spiritual care counselors
- Registered dietitians (RDs)

Not all settings that offer rehabilitation services have all of these members on their team. Not all patients require the services of all health care team members.

A physician who specializes in rehabilitative medicine is called a **physiatrist**. Most inpatient rehabilitation settings employ physiatrists. A primary care physician may also oversee care for the patient’s medical problems.

Rehabilitation nurses in the inpatient setting coordinate the efforts of health care team members and therefore function as the patient’s case manager. Nurses also create a rehabilitation milieu, which includes (Pryor, 2010):

- Allowing time for patients to practice self-management skills
- Encouraging patients and providing emotional support

TABLE 8-1 NURSE'S ROLE IN THE REHABILITATION TEAM

- Advocates for the patient and family
- Creates a therapeutic rehabilitation milieu
- Provides and coordinates holistic patient care in a variety of health care settings, including the home
- Collaborates with the rehabilitation team to establish expected patient outcomes to develop a plan of care
- Coordinates rehabilitation team activities to ensure implementation of the plan of care
- Acts as a resource to the rehabilitation team having specialized knowledge and clinical skills needed to care for patient with chronic and disabling health problems
- Communicates effectively with all members of the rehabilitation team, including the patient and family
- Plans continuity of care when the patient is discharged from the health care facility
- Evaluates the effectiveness of the interdisciplinary plan of care for the patient and family

Adapted from Association of Rehabilitation Nurses. (2008). *Standards and scope of rehabilitation nursing practice*. Glenview, IL: Author.

- Protecting patients from embarrassment (e.g., bowel training)
- Making the inpatient unit a more homelike environment

Table 8-1 summarizes the nurse's role as part of the rehabilitation team. Because of an increase in the need for older adult rehabilitation, some nurses specialize in gerontologic rehabilitation (Association of Rehabilitation Nurses, 2008b). Nurses and other health care professionals may be designated as **rehabilitation case managers** in the home or in acute care settings. Case management is described in Chapter 1.

Physical therapists intervene to help the patient achieve self-management by focusing on gross mobility skills (e.g., by facilitating ambulation and teaching the patient to use a walker) (Fig. 8-1). They may also teach techniques for performing certain ADLs, such as transferring (e.g., moving into and out of bed), ambulating, and toileting, and can assist with cognitive retraining (often for patients with TBI). Physical therapy assistants (PTAs) may be employed to help the PT.

Occupational therapists work to develop the patient's fine motor skills used for ADL self-management, such as those required for eating, hygiene, and dressing. OTs also teach patients how to perform independent living skills, such as cooking and shopping. Many inpatient rehabilitation facilities have fully furnished and equipped apartments where patients can practice independent living skills in a mock setting under supervision. To accomplish these outcomes, OTs teach skills related to coordination (e.g., hand movements) and cognitive retraining (Fig. 8-2). Occupational therapy assistants (OTAs) may be available to help the OT.

Speech-language pathologists (SLPs) evaluate and retrain patients with speech, language, or swallowing problems. *Speech* is the ability to say words, and *language* is the ability to understand and put words together in a meaningful way. Some patients, especially those who have experienced a head injury or stroke, have difficulty with both speech and language. Those who have had a stroke also may have dysphagia (difficulty with swallowing). SLPs provide screening and testing for dysphagia. If the patient has this problem, the SLP recommends appropriate foods and feeding techniques.

FIG. 8-1 A physical therapist helping a patient ambulate with a walker.

FIG. 8-2 A registered occupational therapist working with a patient on improving hand strength.

Speech-language pathology assistants (SLPAs) may be employed to help the SLP.

PTs, OTs, and SLPs are collectively referred to as *rehabilitation therapists*. Assistants to PTs, OTs, and SLPs are called *rehabilitation assistants*. **Restorative aides**, usually in the nursing department, continue the rehabilitation therapy plan of care when therapists are not available. This model of care is common in long-term care settings, such as nursing homes.

Recreational or **activity therapists** work to help patients continue or develop hobbies or interests. These therapists often coordinate their efforts with those of the OT.

Cognitive therapists, usually neuropsychologists, work primarily with patients who have experienced head injuries with cognitive impairments. These therapists often use computers to assist with cognitive retraining.

Registered dietitians (RDs) may be needed to ensure that patients meet their nutritional needs. For example, for patients who need weight reduction, a restricted calorie diet can be planned. For patients who need additional calories or other nutrients, including vitamins, nutritionists can plan a patient-specific diet.

As their name implies, **nursing assistants** or **nursing technicians** assist in the care of patients. These members of the rehabilitation team are under the direct supervision of the registered nurse (RN) or licensed practical or vocational nurse (LPN or LVN).

Various counselors are helpful in promoting community reintegration of the patient and acceptance of the disability or chronic illness. **Social workers** help patients identify support services and resources, including financial assistance, and coordinate transfers to or discharges from the rehabilitation setting. **Clinical psychologists** also counsel patients and families on their psychological problems and on strategies to cope with disability. They may also perform a battery of cognitive assessments. **Spiritual counselors**, usually members of the clergy, specialize in spiritual assessments and care.

Vocational counselors assist with job placement, training, or further education. Work-related skills are taught if the patient needs to change careers because of the disability. If the patient has not yet completed high school, tutors may help with completion of the requirements for graduation.

Depending on the patient's health care needs, additional team members may be included in the rehabilitation program, such as the geriatrician, respiratory therapist, pharmacist, and prosthetist. Interdisciplinary team conferences for planning care and evaluating the patient's progress are held regularly with the patient, family members and significant others, and health care providers. The interdisciplinary patient record is shared and read by all team members.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

History

Collect the history of the patient's present condition, any current drug therapy, and any treatment programs in progress. Begin by obtaining general background data about the patient and family. This information includes cultural practices and the patient's home situation. In collaboration with the occupational therapist, the nurse or case manager addresses the layout of the home. Together they discuss whether the physical layout at home, such as stairs or the width of doorways, will present a problem to the patient after discharge.

Assess the patient's usual daily schedule and habits of everyday living. These include hygiene practices, eating, elimination, sexual activity, and sleep. Ask about the patient's preferred method and time of bathing and hygiene activity. In assessing dietary patterns, note food likes and dislikes. Also, obtain information about bowel and bladder function and the normal pattern of elimination.

In assessing sexuality patterns, ask about changes in sexual function since the onset of the disability. The patient's current and previous sleep habits, patterns, usual number of hours of sleep, and use of hypnotics are also assessed. Question whether the patient feels well rested after sleep. Sleep patterns have a significant impact on activity patterns. The assessment of activity patterns focuses on work, exercise, and recreational activities.

CONSIDERATIONS FOR OLDER ADULTS

Older adults who need rehabilitation often have other chronic diseases that need to be managed, including diabetes mellitus, coronary artery disease, osteoporosis, and arthritis. These health problems added to the normal physiologic changes associated with aging predispose the older adult to falls, pressure ulcers, and pneumonia. When discharged from a hospital setting, some older patients are undernourished, which causes weakness and fatigue. The longer the hospital stay, the more debilitated the older adult can become.

Health teaching may be challenging because some older patients may have beginning cognitive changes, including short-term memory loss. Sensory losses, like vision and hearing, also affect their ability to give an accurate history or grasp new information.

Physical Assessment/Clinical Manifestations

Upon admission for baseline and every day thereafter according agency policy and type of setting, collect the physical assessment data systematically according to major body systems (Table 8-2). The focus of the assessment related to

TABLE 8-2 ASSESSMENT OF PATIENTS IN REHABILITATION SETTINGS

BODY SYSTEM	RELEVANT DATA
Cardiovascular system	Chest pain Fatigue Fear of heart failure
Respiratory system	Shortness of breath or dyspnea Activity tolerance Fear of inability to breathe
Gastrointestinal system and nutrition	Oral intake, eating pattern Anorexia, nausea, and vomiting Dysphagia Laboratory data (e.g., serum prealbumin level) Weight loss or gain Bowel elimination pattern or habits Change in stool (constipation or diarrhea) Ability to get to toilet
Renal-urinary system	Urinary pattern Fluid intake Urinary incontinence or retention Urine culture and urinalysis
Neurologic system	Motor function Sensation Perceptual ability Cognitive abilities
Musculoskeletal system	Functional ability Range of motion Endurance Muscle strength
Integumentary system	Risk for skin breakdown Presence of skin lesions

rehabilitation and chronic disease is on the functional abilities of the patient.

Cardiovascular and Respiratory Assessment. An alteration in cardiac status may affect the patient's cardiac output or cause activity intolerance. Assess associated signs and symptoms of decreased cardiac output (e.g., chest pain, fatigue). If present, determine when the patient experiences these symptoms and what relieves them. The physician may prescribe a change in drug therapy or may prescribe a prophylactic dose of nitroglycerin to be taken before the patient resumes activities. Collaborate with the physician and appropriate therapists to determine whether activities need to be modified.

For the patient showing fatigue, the nurse and patient plan methods for using limited energy resources. For instance, frequent rest periods can be taken throughout the day, especially before performing activities. Major tasks could be performed in the morning because most people have the most energy at that time.

A hindrance to rehabilitation for patients with cardiac disorders is fear, particularly for older adults. These patients may have survived a life-threatening experience (e.g., myocardial infarction) and may be so afraid of recurrence or death that they are unable or unwilling to resume any activity. They usually benefit from participation in a structured cardiac rehabilitation program. (See Chapter 40 for a complete description of cardiac rehabilitation.)

Ask the patient whether he or she has shortness of breath, chest pain, or severe weakness and fatigue during or after activity. *Determine the level of activity that can be accomplished without these symptoms.* For example, can the patient climb one flight of stairs without shortness of breath or does shortness of breath occur after climbing only two steps?

The fear associated with any inability to breathe normally can make a person dependent in many aspects of life. Some problems related to disorders of the respiratory system can be resolved or diminished, but some chronic diseases, such as emphysema, often continue to worsen.

Gastrointestinal and Nutritional Assessment. Monitor the patient's oral intake and pattern of eating. Also, assess for the presence of anorexia, dysphagia, nausea, vomiting, or discomfort that may interfere with oral intake. Determine whether the patient wears dentures and, if so, whether they fit. Review the patient's height, weight, hemoglobin and hematocrit levels, serum prealbumin, and blood glucose levels (see Chapter 63 for discussion of how to perform a nutritional assessment). Weight loss or weight gain is particularly significant and may be related to an associated disease or to the illness that caused the disability.

Bowel elimination habits vary from person to person. They are often related to daily job or activity schedules, dietary patterns, age, and family or cultural background. Elimination habits may be difficult to assess, because many nurses are hesitant to request (and many patients are afraid to volunteer) information pertaining to elimination. Ask about usual bowel patterns before the injury or the illness.

Note any changes in the patient's bowel routine or stool consistency. The most common problem for rehabilitation patients is constipation. In their classic best practice guidelines, the Association of Rehabilitation Nurses (2002) defines constipation as the passage of hard, dry stool less than 3 times a week or significant change in the patient's usual habits for

more than 3 months. Examples of important changes include abdominal fullness and bloating and straining when having a bowel movement.

If the patient reports any alteration in elimination pattern, try to determine whether it is due to a change in diet, activity pattern, or medication use. Bowel habits are always evaluated based on what is normal for that person.

Ask whether the patient can manage bowel function independently. Independence in bowel elimination requires cognition, manual dexterity, sensation, muscle control, and mobility. If the patient requires help, determine whether someone is available at home to provide the assistance. Also assess the patient's and family's ability to cope with any dependency in bowel elimination.

Renal and Urinary Assessment. Ask about the patient's baseline urinary patterns, including the number of times he or she usually voids. Determine whether he or she routinely awakens during the night to empty the bladder (nocturia) or has uninterrupted sleep. Record fluid intake patterns and volume, including the type of fluids ingested and the time they were consumed.

Question whether the patient has ever had any problems with urinary incontinence or retention. Also, monitor laboratory reports, especially the results of the urinalysis and culture and sensitivity, if needed. Urinary tract infections (UTIs) among older adults are often missed because acute confusion may be the only indicator of the infection. Many health care professionals expect older patients to be confused and may not detect this problem. If untreated, UTIs can lead to kidney infection and possible failure.

Neurologic and Musculoskeletal Assessment. In rehabilitation, the neurologic assessment includes motor function, sensation, and cognition. Assess the patient's pre-existing problems, general physical condition, and communication abilities. Patients may have dysphasia (slurred speech) because of facial muscle weakness or may have aphasia (inability to speak or comprehend), usually the result of a cerebral stroke or traumatic brain injury (TBI). These communication problems are discussed in detail in the unit on problems of the nervous system.

Determine if the patient has **paresis** (weakness) or **paralysis** (absence of movement). Observe the patient's gait. Identify sensory-perceptual changes, such as visual acuity, that could contribute to the patient's risk for injury. Assess his or her response to light touch, hot or cold temperature, and position change in each extremity and on the trunk. Identify levels of decreased sensation. For a perceptual assessment, the nurse evaluates the patient's ability to receive and understand what is heard and seen and the ability to express appropriate motor and verbal responses. During this portion of the assessment, begin to assess short-term and long-term memory.

Assess the patient's cognitive abilities, especially if there is a head injury or stroke. Several tools are available to evaluate cognition. One of the most common is the Mini-Mental State Examination, which is described in detail in Chapter 44.

As with other body systems, nursing assessment of the musculoskeletal system focuses on function. Assess the patient's musculoskeletal status, response to the impairment, and demands of the home, work, or school environment. Determine the patient's endurance level, and measure active and passive joint range of motion (ROM). Review the results of manual muscle testing by physical therapy, which identifies

the patient's ROM and resistance against gravity. In this procedure, the therapist determines the degree of muscle strength present in each body segment.

Skin Assessment. Identify actual or potential interruptions in skin integrity. To maintain healthy skin, the body must have adequate food, water, and oxygen intake; intact waste-removal mechanisms; sensation; and functional mobility. Changes in any of these variables can lead to rapid and extensive skin breakdown. If the patient cannot protect or maintain the skin, assess and plan for his or her needs.

! NURSING SAFETY PRIORITY

Action Alert

Be sure to remind unlicensed assistive personnel to report changes in the patient's skin promptly, including any new onset of redness. Assess the patient frequently to determine the risk for skin breakdown before it occurs! Older adults are at a very high risk for heel and sacral pressure ulcers.

Most rehabilitation settings use special skin assessment tools to identify patients at risk for skin breakdown. For example, the classic Braden Scale for Predicting Pressure Ulcer Risk (see [Chapter 27](#)) assesses several areas: sensory perception, skin moisture, activity level, nutritional status, and potential for friction and shear.

Other skin risk assessment tools are available. Some tools also include additional indicators of nutritional status, such as the serum prealbumin. When these levels are low, the patient is at high risk for pressure ulcers. Some tools include incontinence and altered mental state as risk factors.

If a pressure ulcer or other change in skin integrity develops, accurately assess the problem and its possible causes. Inspect the skin every 2 hours until the patient learns to inspect his or her own skin several times a day. Measure the depth and diameter of any open skin areas in inches or centimeters, depending on the policy of the facility. Assess the area around the open lesion to determine the presence of cellulitis or other tissue damage. [Chapter 27](#) includes several widely used classification systems for assessing skin breakdown. Determine the patient's knowledge about the cause and treatment of skin breakdown, as well as his or her ability to inspect the skin and participate in maintaining skin integrity.

In most health care agencies, a skin assessment and documentation tool ("skin sheet") is used to keep track of each area of skin breakdown. A baseline assessment is conducted on admission to the agency, and the form is updated periodically depending on the agency's policy and the nurse's judgment. In most long-term care, acute care, and rehabilitation settings, and with the patient's (or family's if the patient cannot communicate) permission, photographs of the skin are taken on admission and at various intervals for documentation.

? NCLEX EXAMINATION CHALLENGE

Physiological Integrity

An 88-year-old woman is admitted for cardiac rehabilitation after an insertion of two coronary artery stents. While ambulating with her walker, the client reports chest pain. What is the nurse's first action?

- Take her heart rate and blood pressure.
- Stop her activity and provide a rest period.
- Call her health care provider immediately.
- Perform a stat electrocardiogram.

Functional Assessment

Functional ability refers to the ability to perform **activities of daily living (ADLs)**, such as bathing, dressing, feeding, and ambulating, and **independent living skills**, including using the telephone, shopping, preparing food, and housekeeping. These latter skills are sometimes referred to as **instrumental activities of daily living (IADLs)**. Functional assessment tools are used to assess a patient's abilities. Rehabilitation nurses, physiatrists, or rehabilitation therapists complete one or more of these assessment tools based on the patient's abilities and the policy of the health care setting.

One uniform data system used for outcome data collection across the United States is the Functional Independence Measure (FIM) developed by Granger and Gresham (1984). As a basic indicator of the severity of a disability, the FIM attempts to quantify what the person actually does, whatever the diagnosis or impairment. It does not measure what a person should do or how the person would perform under a different set of circumstances. To eliminate the bias of a particular discipline, the assessment may be performed by trained clinicians. The entire assessment may be performed by one person, or certain categories may be completed by professionals from various disciplines.

Categories for assessment are self-care, sphincter control, mobility and locomotion, communication, and cognition. Scoring is done with numbers that use predetermined criteria for measurement. The patient is evaluated when he or she is admitted to and discharged from a rehabilitation institution and at other specified times to determine progress. The FIM system has also been adapted for use in other health care settings, including acute care and home care, and is available in multiple languages.

In U.S. long-term care settings, the interdisciplinary Minimum Data Set (MDS) is used to assess patients (residents) in nursing homes. The resident's motor ability, sensation, and cognition are evaluated, as well as the overall health status. Similar to the FIM, all health care team members involved in the resident's care record their assessments on the MDS and the RN coordinates the comprehensive assessment.

Psychosocial Assessment

Assess the patient's body image and self-esteem through verbal indicators and descriptions of self-care. Encourage the family to allow the patient to perform as many functions as possible independently to build feelings of self-worth.

Assess the patient's use of defense mechanisms and manifestations of anxiety. To assess the patient's response to loss, ask him or her to describe feelings concerning the loss of a body part or function. Assess for the presence of any stress-related physical problem. Some patients have symptoms of depression, such as fatigue, a change in appetite, or feelings of powerlessness. See [Chapter 9](#) for a more thorough discussion of loss and grieving and [Chapter 3](#) for a brief description of depression among the older adult population.

Determine the availability of support systems for the patient. The major support system is typically the family or significant others. Patients who do not have these support systems are more likely to develop depression. Assess the patient's spiritual and/or religious needs, and refer to an appropriate health care team member as needed.

Vocational Assessment

To assist patients in maximizing functional status, encourage them to resume usual activities. Vocational counselors can help patients find meaningful training, education, or employment after discharge from the rehabilitation setting, if needed.

Patients in the United States should be informed about the Americans with Disabilities Act, which was passed by Congress in 1991 to prevent employer discrimination against disabled people. The employer must offer *reasonable* assistance to a disabled employee to allow him or her to perform the job. For example, if an employee has a severe hearing loss, the employer may need to hire an interpreter for sign language. Workers have a right to ask for special adaptations based on their disabilities.

The rehabilitation team assesses the cognitive and physical demands of the patient's job to determine whether he or she can return to the former job or whether retraining in another field is necessary. The physical demands of jobs range from light in sedentary occupations (0 to 10 lbs often lifted) to heavy (more than 100 lbs often lifted). The nurse must also consider other aspects of the job, such as mobility or senses required (e.g., hearing).

Job analysis also involves assessing the work environment of the patient's former job. Collaborate with the vocational counselor to determine whether the environment is conducive to the patient's return. Job modifications may be needed to accommodate the patient at work. If an injured worker requires vocational rehabilitation, refer him or her to vocational rehabilitation personnel to evaluate present skills and learn new skills for employment if needed. In most states, Workers' Compensation insurance helps support vocational rehabilitation.

ANALYSIS

Regardless of age or specific disability, these priority patient problems are common. Additional problems depend on the patient's specific chronic illness or disability.

1. Decreased physical mobility related to neuromuscular impairment, sensory-perceptual impairment, and/or chronic pain
2. Decreased functional ability related to neuromuscular impairment and/or perceptual or cognitive impairment
3. Risk for Impaired Skin Integrity related to altered sensation and/or altered nutritional state
4. Urinary incontinence or Urinary Retention related to neurologic dysfunction and/or trauma or disease affecting spinal cord nerves
5. Constipation related to neurologic impairment, inadequate nutrition, or decreased mobility

PLANNING AND IMPLEMENTATION

Improving Physical Mobility

Planning: Expected Outcomes. The patient with chronic illness or disability is expected to reach a level of physical mobility that allows him or her to function independently with or without assistive devices. In addition, the patient is expected to be free of complications of immobility.

Interventions. Most problems requiring rehabilitation relate to decreased physical mobility. For example, patients

with neurologic disease or injury, amputations, arthritis, and cardiopulmonary disease usually experience some degree of immobility. Coordinate care with physical and occupational therapists as the key rehabilitation team members in helping patients meet their mobility outcomes. Depending on the setting, patients initially spend 3 to 6 hours at least 5 days a week working in rehabilitation therapy departments to regain function and self-management skills.

Safe Patient Handling Practices. Before they learn to become independent, patients with decreased mobility in any health care setting or at home often need assistance with bed mobility and transfers, such as from a bed to a chair, commode, or wheelchair. Patients may not be able to bear full weight, have inadequate balance, and/or are very obese. For many years, nurses relied on "body mechanics" to prevent staff injury when moving patients or assisting them to move. This traditional, but outdated, approach was based on the belief that correct body positioning by staff members would protect them from the force of lifting and moving. For example, if the patient could not bear weight or did not have sufficient balance (e.g., quadriplegic spinal cord injury), nurses and therapists used a "bear hug" technique to lift the patient from bed to chair or back again. Obese patients were also lifted with multiple staff assistance.

Heavy lifting and dependent transfers by staff members have resulted in a very high incidence of **work-related musculoskeletal disorders (MSDs)**, most often chronic back injuries, which can be prevented. As a response to this costly problem, the National Institute for Occupational Safety and Health (NIOSH) recently published evidence-based guidelines for safe patient handling. Based on this document, the American Nurses Association, in partnership with NIOSH and the Veterans Health Administration, developed a curriculum for all nursing students and practicing nurses on how to safely handle and move patients in any health care setting or home environment. In collaboration with other health care team members, nurses assess patient mobility and use best practices for safe patient handling (SPH).

Because each patient has unique needs and characteristics, assess the patient's mobility level using a standardized tool to plan interventions for SPH. An example of an appropriate assessment tool for this purpose is shown in Fig. 8-3. Before moving the patient, assess his or her environment for potential hazards that could cause injury, such as a slippery or uneven floor.

Use these general SPH practices, and teach to staff members:

- Maintain a wide, stable base with your feet.
- Put the bed at the correct height—waist level while providing direct care and hip level when moving patients.
- Try to keep the patient or work directly in front of you to prevent your spine from rotating.
- Keep the patient as close to your body as possible to prevent reaching.

The Veterans Health Administration and many other health care systems follow a no-lift or limited-lift policy for all of their facilities due in large part to technology. That means that nurses and therapists either rely on the patient to independently move and transfer or use a powered, mechanical full-body lift that is either ceiling- or wall-mounted or

Assessment Tool and Care Plan for Safe Patient Handling and Movement

I. Patient's Level of Assistance

- ☐ Independent—Patient performs task safely, with or without staff assistance, with or without assistive devices.
☐ Partial Assist—Patient requires no more help than standby, cueing, or coaxing, or caregiver is required to lift no more than 35 lbs of a patient's weight.
☐ Dependent—Patient requires nurse to lift more than 35 lbs of the patient's weight, or patient is unpredictable in the amount of assistance offered. In this case, assistive devices should be used.

An assessment should be made before each task if the patient has a varying level of ability to assist because of medical reasons, fatigue, medications, etc. When in doubt, assume the patient cannot assist with the transfer/repositioning.

II. Weight-Bearing Capability

- ☐ Full
☐ Partial
☐ None

III. Bilateral Upper-Extremity Strength

- ☐ Yes
☐ No

IV. Patient's Level of Cooperation and Comprehension

- ☐ Cooperative—May need prompting; able to follow simple commands.
☐ Unpredictable or variable (patient whose behavior changes frequently should be considered unpredictable)—Not cooperative or unable to follow simple commands.

V. Weight _____ Height _____

Body Mass Index (BMI) (needed if patient's weight is over 300 lbs)*
If BMI exceeds 50, institute Bariatric Algorithms.

The presence of the following conditions is likely to affect the transfer/repositioning process and should be considered when identifying equipment and techniques needed to move the patient.

VI. Check Applicable Conditions Likely to Affect Transfer/Repositioning Techniques

- | | | |
|---|--|---|
| ☐ Hip/knee/shoulder replacements | ☐ Respiratory/cardiac compromise | ☐ Fractures |
| ☐ History of falls | ☐ Wounds affecting transfer/positioning | ☐ Splints/traction |
| ☐ Paralysis/paresis | ☐ Amputation | ☐ Severe osteoporosis |
| ☐ Unstable spine | ☐ Urinary/fecal stoma | ☐ Severe pain/discomfort |
| ☐ Severe edema | ☐ Contractures/spasms | ☐ Postural hypotension |
| ☐ Very fragile skin | ☐ Tubes (IV, chest, etc.) | |

Comments: _____

VII. Appropriate Lift/Transfer Devices Needed

Vertical Lift:

Horizontal Lift:

Other Patient-Handling Devices Needed:

Sling Type

- | | | |
|---------------------------------|---|---------------------------------------|
| ☐ Seated | ☐ Seated (Amputee) | ☐ Standing |
| ☐ Supine | ☐ Ambulation | ☐ Limb Support |

Sling Size _____

Signature _____ Date _____

*If patient weighs more than 300 lbs, the BMI is needed. For online BMI table and calculator, see http://www.nhlbi.nih.gov/guidelines/obesity/bmi_tbl.htm.

FIG. 8-3 Example of a tool to assess physical mobility.

portable (mobile) (Fig. 8-4). Most lifts use slings that are comfortable, safe, and easy to apply. Electric-powered, portable sit-to-stand devices are also available.

In 2002, the U.S. government requested that nursing homes voluntarily use mechanical lifts rather than manual transfers. Instead of a no-lift policy, though, some long-term care facilities limit lifting to 35 pounds (15.9 kg). These changes involve intensive staff training and compliance to prevent staff injury. Mechanical lifts are also available for home use.

For patients who are learning to become independent in transfer or bed mobility skills, the physical or occupational therapist usually specifies the procedure for these maneuvers. For example, a quadriplegic patient may use a sliding board for transfer, whereas a paraplegic patient may need a wheelchair with removable arms. A patient still in bed may be taught to turn independently using the siderails. In any case, for safety, always plan or teach the patient to plan the transfer technique before initiating it. The desired outcome is that the patient will eventually be able to transfer independently and safely.

Basic techniques for teaching the patient how to transfer from a bed to a chair or wheelchair (and vice versa) are identified in Chart 8-1. Teach these techniques to the family member or other caregiver who will be supervising the patient at home. Additional information about transfers can be found in basic nursing textbooks.

FIG. 8-4 Example of powered, mechanical full-body lift.

! NURSING SAFETY PRIORITY

Critical Rescue

Before any transfer, carefully observe for potential problems. Orthostatic, or postural, hypotension is a common problem in rehabilitation settings and contributes to falls, which are common for any patient with impaired mobility. If the patient moves from a lying to a sitting or standing position too quickly, his or her blood pressure drops; as a result, he or she becomes dizzy or faints. This problem is worsened by antihypertensive drugs, especially in older adults. To prevent this situation, help the patient change positions slowly, with frequent rest periods to allow the blood pressure to stabilize. If needed, measure blood pressure with the patient in the lying, sitting, and standing positions to examine the differences. Orthostatic hypotension is indicated by a drop of more than 20 mm Hg in systolic pressure or 10 mm Hg in diastolic pressure between positions. Notify the health care provider and the therapists about this change.

If the patient has problems maintaining blood pressure while out of bed, the physical therapist may start him or her on a tilt table to gradually increase tolerance. A low blood pressure is a particularly common problem for patients who are quadriplegic because they have a delayed blood flow to the brain and upper part of the body.

Weight gain is another potential problem when rehabilitation patients have impaired mobility. Excessive weight hinders transfers both for the nurse or the therapist who is assisting and for the patient who is learning to transfer independently. Weight is usually checked every week to monitor gains or losses.

Gait Training. The physical therapist works with patients for gait training if they are able to ambulate. While regaining the ability to ambulate, patients may need to use assistive devices, such as a variety of canes or walkers (Fig. 8-5). The specific device selected for each patient depends on the amount of weight bearing that is allowed or tolerated. For example, a stroke patient who has problems with maintaining balance or a steady gait when walking might need a walker. Some patients use walkers with rollers made of tennis ball materials; others who fatigue easily may need a walker with a built-in seat to rest at intervals. A patient who had a total knee replacement 6 weeks ago may be able to use a straight (also called single-point) cane.

When working with patients who are using these devices, also known as **ambulatory aids**, the physical therapist ensures that there is a level surface on which to walk. The patient wears a transfer (gait) belt for safety so that the therapist or

CHART 8-1 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Transfer Techniques for Stroke Patients

Bed to Wheelchair or Chair

- Be sure that the patient wears a transfer (gait) belt.
- Place the chair at an angle to the bed on the patient's strong side.
- Lock the wheelchair brakes, or secure the chair position.
- While holding on to the transfer belt, ask the patient to stand and move his or her strong hand to the armrest.
- Remind the patient to keep his or her body weight forward, and pivot.
- When the patient's legs touch the chair edge, guide the patient into a sitting position in the chair.
- Keep the transfer belt in place for transfer back into bed.

Wheelchair or Chair to Bed

- Place the chair with the patient's strong side next to the bed.
- Lock the wheelchair brakes, or secure the chair position.
- Ask the patient to stand, and move his or her strong hand to the armrest.
- Remind the patient to keep his or her body weight forward, and pivot.
- When the patient's legs touch the bed edge, guide the patient until sitting and then reclining.

FIG. 8-5 Assistive devices for ambulation. Assistive devices vary in the amount of support they provide. A straight (single-point) cane provides less support than a walker (**A**) or quadripod cane (**B**).

CHART 8-2 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Gait Training with Selected Ambulatory Aids

Walker Assisted

- Apply a transfer belt around the patient's waist.
- Guide the patient to a standing position.
- Remind the patient in placing both hands on the walker.
- Ensure that the patient is well balanced.
- Teach the patient repeatedly to perform this sequence:
 - Lift the walker.
 - Move the walker about 2 feet forward, and set it down on all legs.
 - While resting on the walker, take small steps.
 - Check balance.
 - Repeat the sequence.

Cane Assisted

- Apply a transfer belt around the patient's waist.
- Guide the patient to a standing position.
- Be sure the cane is at the height of the patient's wrist when the arm is placed at his or her side. (Many canes can be adjusted to the required height.)
- Remind the patient to place his or her strong hand on the cane.
- Ensure that the patient is well balanced.
- Teach the patient to perform this sequence repeatedly:
 - Move the cane and weaker leg forward at the same time.
 - Move the stronger leg one step forward.
 - Check balance and repeat the sequence.

nurse can guide him or her during ambulation to help prevent falls. Use of transfer belts are recommended as one of the best practices for safe patient handling (Waters & Rockefeller, 2010).

Reinforce the physical therapist's instructions and encourage practice, with the outcome being to walk independently with or without an assistive device. Older patients typically use a walker, with or without rollers, for a broader base of support. Younger or minimally impaired patients often progress to the use of a hemi-cane or straight cane. [Chart 8-2](#) outlines best practices for patient safety when teaching patients how to use ambulatory aids.

Some patients never regain the ability to walk because of their impairment, such as advanced multiple sclerosis or complete high spinal cord injury. They may become wheelchair dependent and need to learn wheelchair or motorized scooter mobility skills. With the help of physical and occupational therapy, most patients can learn to move anywhere in a wheelchair or scooter. For example, quadriplegic patients often use motorized wheelchairs that can be directed and propelled by moving their head or blowing into a device. Patients with multiple sclerosis often use scooters to get around.

During the rehabilitation phase, patients are at risk for complications of immobility. [Table 8-3](#) lists some of the

common complications and strategies the nurse can use to help prevent each complication. Implementing range-of-motion (ROM) routines, adhering to schedules for turning and repositioning, and maintaining skin care are constant components of rehabilitation nursing care to prevent complications of immobility. The key is to increase mobility.

One way to increase mobility, even with patients who are bedridden, is through ROM exercises. ROM techniques are beneficial for any patient with decreased mobility. Although simple ROM techniques are presented in basic nursing textbooks, a few key principles are pertinent to rehabilitation nursing care:

- The human body contains more joints than simply the knees, hips, elbows, and shoulders. For ROM techniques to be effective in preventing musculoskeletal contractures, the patient must exercise all joints, including each joint of the fingers, hands, toes, and so forth.
- In performing ROM activities, the nurse or patient performs full-range movement of each joint at least five times and completes the entire process at least three times daily.
- The nurse does not move the joints beyond the point at which the patient expresses pain or beyond the point at which resistance occurs.

TABLE 8-3 PREVENTION OF THE COMMON COMPLICATIONS OF IMMOBILITY

BODY SYSTEM	COMPLICATIONS	PREVENTION
Musculoskeletal	Contractures Footdrop Osteoporosis Susceptibility to fractures Muscular atrophy	Foot support while in bed, range-of-motion exercises, high-top tennis shoes Ambulation if possible (walking) Other weight-bearing exercises
Gastrointestinal	Constipation	Sitting in an upright position Increased activity level Increased fluid and fiber intake
Cardiovascular	Decreased cardiac output Increased venous stasis Thrombus formation Embolism	Range-of-motion exercises Exercise Antiembolism stockings Avoidance of leg massage Low-molecular-weight heparin or other anticoagulant
Neurologic	Disorientation	Sleep-wake schedule in accord with light-dark pattern Reorientation (to person, place, time) Control of sensory stimulation
Renal/urinary	Calculi	Decreased dietary calcium level, if needed Increased fluid intake Ensuring low post-void residuals Intermittent catheterization instead of indwelling if possible
Respiratory	Infection Pneumonia	Frequent oral hygiene Frequent repositioning in wheelchair or bed Breathing exercises
Integumentary (Skin)	Pressure ulcers	Frequent repositioning in wheelchair or bed Pressure reduction or relief devices (in bed and wheelchair) Meticulous skin care Adequate nutrition Frequent skin assessments

Patients with decreased mobility who are able to follow directions are taught by the nurse and the physical therapist to perform active or active-assisted ROM exercises.

Increasing Functional Mobility

Planning: Expected Outcomes. The patient with chronic illness or disability is expected to increase functional ability in self-care and other self-management skills with or without assistive/adaptive devices.

Interventions. ADLs, or self-care activities, include eating, bathing, dressing, grooming, and toileting. Encourage the patient to perform as much self-care as possible. Be patient because he or she often takes more time to complete a task than healthy adults do. Collaborate with the occupational therapist (OT) to identify ways in which self-care activities can be modified so the patient can perform them independently and with minimal frustration if possible. For example, the OT teaches a hemiplegic patient to put on a shirt by first placing the affected arm in the sleeve and then putting the unaffected arm in the appropriate sleeve. Slip-on shoes or shoes with Velcro straps may be recommended for some patients. Encourage patients to practice, and allow them time to try to be independent in ADLs.

In long-term care (LTC) settings (e.g., nursing homes), federal regulations require that residents not lose their functional skills while they are in the facility. Therefore most facilities have developed *restorative nursing* programs and have coordinated these programs with rehabilitation therapy and activity therapy. The focus of this coordinated effort includes:

- Bed mobility
- Walking

- Transfers
- Dressing
- Grooming
- Active range of motion
- Communication

A variety of devices are available for patients with chronic illness and disability for *assisting with self-care*. An **assistive/adaptive device**, or self-care support device, is any item that enables the patient to perform all or part of an activity independently and safely. Examples include long-handled shoe-horns and reachers to prevent bending and losing one's balance. Table 8-4 identifies common devices and describes their use.

Many department stores and large pharmacies carry clothing and assistive/adaptive devices designed for patients with disabilities. The occupational therapist determines specific patient needs for this equipment. Collaborate with the occupational therapist to look for creative and inexpensive alternatives to meeting these needs. For example, barbecue tongs may be used as "reachers" for pulling up pants or obtaining items on high shelves. A foam curler with the plastic insert removed may be placed over a pencil or eating utensil to make a built-up device. The patient might use an extended shoe-horn to operate light switches from wheelchair height. Hook-and-loop fasteners (Velcro) sewn on clothes can prevent the frustrations caused by buttons and zippers.

Assistive technology has further increased the ability for disabled patients to care for themselves using electronic equipment. For example, telephones can be dialed using a voice-activated dialing device. Computer keyboards also can be operated by voice-activation devices.

TABLE 8-4 EXAMPLES AND USES OF COMMON ASSISTIVE/ADAPTIVE DEVICES

DEVICE	USE
Buttonhook	Threaded through the buttonhole to enable patients with weak finger mobility to button shirts Alternative uses include serving as pencil holder or cigarette holder
Extended shoehorn	Assists in the application of shoes for patients with decreased mobility Alternative uses include turning light switches off or on while patient is in a wheelchair
Plate guard and spork (spoon and fork in one utensil)	Applied to a plate to assist patients with weak hand and arm mobility to feed themselves; spork allows one utensil to serve two purposes
Gel pad	Placed under a plate or a glass to prevent dishes from slipping and moving Alternative uses include placement under bathing and grooming items to prevent them from moving
Foam buildups	Applied to eating utensils to assist patients with weak hand grasps to feed themselves Alternative uses include application to pens and pencils to assist with writing or over a buttonhook to assist with grasping the device
Hook and loop fastener (Velcro) straps	Applied to utensils, a buttonhook, or a pencil to slip over the hand and provide a method of stabilizing the device when the patient's hand grasp is weak
Long-handled reacher	Assists in obtaining items located on high shelves or at ground level for patients who are unable to change positions easily
Elastic shoelaces or Velcro shoe closure	Prevents the need for tying shoes

Fatigue often occurs with chronic and disabling conditions. Therefore collaborate with the occupational therapist to assess the patient's self-care abilities and to determine possible ways of *conserving energy*. Coordinate with the therapist to develop strategies for energy conservation after evaluating the patient's self-care routines. Preparation for ADLs can help reduce effort and energy expenditure (e.g., gathering all necessary equipment before starting grooming routines). If a patient has high energy levels in the morning, he or she can be taught to schedule energy-intensive activities in the morning rather than later in the day or evening. Spacing activities is also helpful for conserving energy. In addition, allowing time to rest before and after eating and toileting decreases the strain on energy level.

Maintaining Skin Integrity

Planning: Expected Outcomes. The patient with chronic illness or disability is expected to have intact skin.

DECISION-MAKING CHALLENGE

Evidence-Based Practice; Safety

A 70-year old man is admitted to an inpatient facility for rehabilitation after a right knee replacement for severe osteoarthritis from obesity. He lost 52 pounds before having surgery 2 days ago because his left knee also is arthritic. The patient lives alone in a third-floor apartment and has a daughter nearby who visits at least twice a week. His wife recently died, and he does not cook. His favorite food is hamburgers and French fries from McDonald's. He is retired from his manufacturing job but works part-time at Wal-Mart as a greeter. As his nurse, you complete his admission assessment.

1. What are this patient's priority problems?
2. With what health care team members will you need to collaborate?
3. What do you need to assess before planning how to safely move this patient?
4. What safe patient handling practices would you need to use?
5. What type of ambulatory assistive device would be most appropriate for him at this time?

Interventions. The best intervention to prevent skin breakdown is frequent position changes in combination with adequate skin care and sufficient nutritional intake. Teach staff to turn and reposition all patients at least every 2 hours if they are unable to perform this activity. This time frame may not be sufficient for people who are frail and have thin skin, especially older adults. To determine the best turning schedule, assess the patient's skin condition during each turning and repositioning. For example, if the patient has been sleeping for 2 hours and the nursing assistant decides to postpone turning for 1 hour, reddened areas over the bony prominences may be present. If reddened areas do not fade within 30 minutes after pressure relief or do not blanch, they may be classified as pre-ulcer areas, or stage I pressure areas (see Chapter 27).

Patients who sit for prolonged periods in a wheelchair need to be repositioned at least every 1 to 2 hours. Each patient is evaluated by the physical or occupational therapist for the best seating pad or cushion that is comfortable yet reduces pressure on bony prominences. Patients who are able are taught to perform "wheelchair push-ups" by using their arms to lift their buttocks off the wheelchair seat for 10 seconds or longer every hour, or more often if needed. The physical therapist helps them strengthen their arm muscles in preparation for performing wheelchair push-ups.

If the patient wears high-top tennis shoes for foot positioning to prevent footdrop, remove the shoes and assess for pressure areas every 2 hours. Many patients with neurologic problems have decreased or absent sensation and may not be able to feel the discomfort of increased pressure. Also, check patients who are sitting in wheelchairs for signs of pressure, especially on the lower legs where the leg of the wheelchair could rub against the skin.

Adequate skin care is an essential component of prevention. Perform or assist patients in completing skin care each time they are turned, repositioned, or bathed. Delegate and supervise skin care to unlicensed assistive personnel (UAP), including cleaning soiled areas, drying carefully, and applying a moisturizer. If a patient is incontinent, use topical barrier creams or ointments to help protect the skin from moisture, which can contribute to skin breakdown. To prevent damage

to the already fragile capillary system, teach UAP to avoiding rubbing reddened areas. Instead, carefully observe the areas for further breakdown and relieve pressure on the areas as much as possible. Bed pillows are often good pressure-relieving devices. (See Chapter 27 for a complete discussion of skin care interventions.)

Sufficient nutrition is needed both to repair wounds and to prevent pressure ulcers. Collaborate with the registered dietitian (RD) to assess the patient's food selection and ensure that it contains adequate protein and carbohydrates. Both the nurse and the nutritionist closely monitor the patient's weight and serum prealbumin levels. If either of these indices decreases significantly, the patient may need high-protein, high-carbohydrate food supplements (e.g., milkshakes) or commercial preparations. Chapter 63 describes nutritional supplementation in detail.

Pressure-relieving or pressure-reducing devices include waterbeds, gel mattresses or pads, air mattresses, low-air loss overlays or beds, and air-fluidized beds. Mattress overlays, such as air and gel types, and replacement mattresses are often effective in reducing pressure. *The use of any mechanical device (except air-fluidized beds) does not eliminate the need for turning and repositioning.*

Specialty beds are categorized as either "low air loss" or "air fluidized." Air-fluidized therapy (e.g., Clinitron Rite Hite bed) provides the most effective pressure relief by distributing the patient's weight to prevent pressure in any one area. These beds are not often used to prevent skin breakdown because insurers may not reimburse the agency for the use of the bed. Therefore these special beds are more often reserved for severe skin problems that have not healed with the use of a conventional bed or other mechanical device. The primary disadvantage of this therapy is its expense, which may exceed several hundred dollars for each day of use. Patients also report discomfort from the heat generated by the bed. Although air-fluidized beds are heavy to move, lighter and more portable versions are available for home use. The cost of air-fluidized therapy is reimbursed by some health insurance providers if the bed is deemed medically necessary for the patient's skin problem.

Establishing Urinary Continence

Planning: Expected Outcomes. Most patients with chronic illness or disability are expected to have normal patterns of urinary continence without retention, infection, or incontinence.

Interventions. Neurologic disabilities often interfere with successful bladder control in a patient undergoing rehabilitation. These disabilities result in two basic functional types of neurogenic bladder: overactive (e.g., reflex or spastic bladder) and underactive (e.g., hypotonic or flaccid bladder).

An overactive **spastic** (upper motor neuron) **bladder** causes incontinence with sudden, gushing voids. The bladder does not usually empty completely, and the patient is at risk for urinary tract infection. Neurologic problems affecting the upper motor neuron typically occur in patients with strokes or with high-level spinal cord injuries (cervical) or those above the mid-thoracic region. These injuries result in a failure of impulse transmission from the lower spinal cord areas to the cortex of the brain. Therefore when the bladder fills and transmits impulses to the spinal cord, the patient cannot perceive the sensation. Because there is no injury to

the lower spinal cord and the voiding reflex arc is intact, the efferent (motor) impulse from a distended bladder is relayed and the bladder contracts.

Experimental technology using sacral neuromodulation is being tested with complete spinal cord-injury patients. The results have been positive in preventing urinary incontinence in patients with spastic bladders (Sievert et al., 2010).

An underactive **flaccid** or **areflexic** (lower motor neuron) **bladder** results in urinary retention and overflow (dribbling). Injuries that damage the lower motor neuron at the spinal cord level of S2-4 (e.g., multiple sclerosis, spinal cord injury or tumor below T12) may directly interfere with the reflex arc or may result in inaccurate interpretation of impulses to the brain. The bladder fills, and afferent (sensory) impulses conduct the message via the spinal cord to the brain cortex. Because of the injury, the impulse is not interpreted correctly by the brain's bladder center and there is a failure to respond with a message for the bladder to contract.

Post-Void Residual Assessment. Patients who cannot completely empty their bladder are at risk for post-void residual urine and subsequent possible urinary tract infection. **Post-void residual (PVR)** is the amount of urine remaining in the bladder within 20 minutes after voiding. PVR assessments using a noninvasive ultrasound device called the *BladderScan* are performed by nurses at the bedside. The residual amount measured is accurate if the device is used correctly. It is not accurate when used for morbidly obese patients. The outcome of bladder ultrasonography is to prevent an indwelling urinary catheter. Long-term urinary catheters cause urinary tract infections that are often chronic. A picture of the *BladderScan* device is in Chapter 68 (see Fig. 68-10).

Bladder Retraining. The nurse can teach a variety of techniques to assist the patient in retraining or repatterning voiding, including (Table 8-5):

- Facilitating, or triggering, techniques
- Intermittent catheterization
- Consistent scheduling of toileting routines; "timed void"

These techniques may not be as effective in patients with physiologic changes associated with aging, including stress incontinence in women with weak pelvic floor muscles and overflow incontinence in men with enlarged prostate glands.

Facilitating (triggering) techniques are used to stimulate voiding. If there is an upper motor neuron problem but the reflex arc is intact (reflex bladder pattern), the voiding response can be initiated by any stimulus that sends the message to the spinal cord level S2-4 that the bladder might be full. Such techniques include stroking the medial aspect of the thigh, pinching the area above the groin, massaging the penoscrotal area, pinching the posterior aspect of the glans penis, and providing digital anal stimulation.

When the patient has a lower motor neuron problem, the voiding reflex arc is not intact (flaccid bladder pattern) and additional stimulation may be needed to initiate voiding. Two techniques used to facilitate voiding are the Valsalva maneuver and the Credé maneuver. In teaching the Valsalva maneuver, teach the patient to hold his or her breath and bear down as if trying to defecate. Assist the patient in performing the **Credé maneuver** by placing the patient's hand in a cupped position directly over the bladder area and instructing him

TABLE 8-5 MANAGEMENT OF NEUROGENIC BLADDER

FUNCTIONAL TYPE	NEUROLOGIC DISABILITY	DYSFUNCTION	RE-ESTABLISHING VOIDING PATTERNS
Reflex (spastic)	Upper motor neuron spinal cord injury above T12	Urinary frequency, incontinence but may not empty completely	Triggering or facilitating techniques Drug therapy, as appropriate Bedside bladder ultrasound Intermittent catheterization Consistent toileting schedule Indwelling urinary catheter (as last resort) Increased fluids
Flaccid	Lower motor neuron spinal cord injury below T12 (affects S2-4 reflex arc)	Urinary retention, overflow	Valsalva and Credé maneuvers Increased fluids Intermittent or indwelling urinary catheterization

or her to push inward and downward gently as if massaging the bladder to empty.

Intermittent catheterization may be needed for a flaccid or spastic bladder. Initially, a urinary catheter is inserted to drain urine every few hours—after the patient has attempted voiding and has used the Valsalva and Credé maneuvers. If less than 100 to 150 mL of post-void residual is obtained, the nurse typically increases the interval between catheterizations. *The patient should not go beyond 8 hours between catheterizations.* If intermittent self-catheterization is needed at home after discharge from the rehabilitation facility, the patient may use a specialized appliance to help perform the procedure, especially if he or she has problems with manual dexterity. For patients who cannot catheterize themselves, a family member or significant other may need to be taught how to perform the procedure.

Most patients who need intermittent catheterization have chronic bacteruria (bacteria in the urine with a positive culture), especially those with spinal cord injury (SCI). Unless the patient has symptoms of a urinary tract infection (UTI), such as fever or burning when voiding, the infection is not treated.

! NURSING SAFETY PRIORITY

Action Alert

To *prevent* UTI, teach patients and their caregivers to wash their hands thoroughly before and after catheterization and clean the genital area well. Remind the patient to drink at least 8 to 10 glasses of fluid (two quarts) every day before dinner and avoid carbonated beverages. If patients have indwelling urinary catheters, remind them to drink 15 glasses of fluid (three quarts) each day before dinner and avoid carbonated beverages.

The Natural Medicines Comprehensive Database states that cranberry juice or extract may be effective to help *prevent* UTI (U.S. National Library of Medicine [NIH], 2011). It is not effective for *treating* urinary infection.

Consistent toileting routines may be the best way to re-establish voiding continence when the patient has an overactive bladder. Assess the patient's previous voiding pattern, and determine his or her daily routine. At a minimum, the nurse or nursing staff assists the patient with voiding after awakening in the morning, before and after meals, before and after physical activity, and at bedtime. *Remind the staff to toilet the patient every 2 hours during the day and every 3 to 4 hours at night.*

Consider the patient's bladder capacity, which may range from 100 to 500 mL, as well as mobility limitations and

restrictive clothing. Bladder capacity is determined by measuring urine output. Ensure that the patient is aware of nearby bathrooms at all times or has a call system to contact the nurse or unlicensed assistive personnel for assistance. [Chapter 69](#) also describes methods of achieving bladder control.

Drug Therapy. Drugs are not commonly used for urinary elimination problems. Mild overactive bladder problems may be treated with antispasmodics (e.g., oxybutynin chloride [Ditropan, Apo-Oxybutynin] or flavoxate [Urispas]) to prevent incontinence on a short-term basis. Patients with symptomatic UTIs are managed with short-term antibiotics, such as trimethoprim (Trimplex) or trimethoprim/sulfamethoxazole (Septra, Bactrim). Report the patient's progress in bladder training to the rehabilitation team so that the best decision regarding drug therapy can be made.

Establishing Bowel Continence

Planning: Expected Outcomes. The patient with chronic illness or disability is expected to have regular evacuation of stool without constipation. If possible, patients will control their bowel elimination schedule.

Interventions. Neurologic problems often affect the patient's bowel pattern by causing a reflex (spastic) bowel, a flaccid bowel, or an uninhibited bowel. Bowel retraining programs are designed for each patient to best meet the expected outcomes ([Table 8-6](#)).

Upper motor neuron diseases and injuries, such as a cervical or mid-level spinal cord injury, may result in a reflex (spastic) bowel pattern, with defecation occurring suddenly and without warning. With a reflex pattern, any facilitating or triggering mechanism may lead to defecation if the lower colon contains stool. An example of facilitating or triggering techniques is digital stimulation. For this technique, use a lubricated glove or finger cot and massage the anus in a circular motion for no less than 1 full minute.

! NURSING SAFETY PRIORITY

Critical Rescue

Do not use digital stimulation for patients with cardiac disease because of the risk for inducing a vagal nerve response. This response causes a rapid decrease in heart rate.

Lower motor neuron diseases and injuries interfere with transmission of the nervous impulse across the reflex arc and may result in a flaccid bowel pattern, with defecation occurring infrequently and in small amounts. The use of

TABLE 8-6 MANAGEMENT OF NEUROGENIC BOWEL

FUNCTIONAL TYPE	NEUROLOGIC DISABILITY	DYSFUNCTION	RE-ESTABLISHING DEFECATION PATTERNS
Reflex (spastic)	Upper motor neuron spinal cord injury above T12	Defecation without warning, but may not empty completely	Triggering mechanisms Facilitation techniques High-fiber diet Increased fluids Laxative use (for some patients) Consistent toileting schedule Manual disimpaction
Flaccid	Lower motor neuron spinal cord injury below T12 (affects S2-4 reflex arc)	Usually absent stools for patients with complete lesions	Triggering or facilitating techniques Increased fluids High-fiber diet Suppository use Consistent toileting schedule Manual disimpaction

EVIDENCE-BASED PRACTICE

Necessity of Manual Disimpaction for Bowel Control in Patients with Spinal Cord Injury

Coggrave, M.J., & Norton, C. (2010). The need for manual evacuation and oral laxatives in the management of neurogenic bowel dysfunction after spinal cord injury: A randomized controlled trial of a stepwise protocol. *Spinal Cord*, 48(6), 504-510.

The researchers used a randomized controlled design to test interventions needed to maintain bowel continence among patients who had spinal cord injuries for many years. The 68 volunteers were randomized into an intervention group of 35 and a control group of 33. The control group used their usual bowel management program. The intervention group used oral laxatives and manual disimpaction in a stepwise protocol and in combination. All study participants kept bowel diaries for 6 weeks.

Findings from the study showed that manual disimpaction significantly improved bowel continence more than oral laxatives or other bowel management programs. Some patients needed both laxatives and disimpaction to maintain bowel continence.

Level of Evidence: 1

This study used a randomized controlled design to compare bowel management interventions between a control group and an experimental group that used two specific bowel management interventions—manual disimpaction and oral laxatives.

Commentary: Implications for Practice and Research

This research added to the evidence for planning the best bowel management protocol for spinal cord-injured patients. Nurses can use this information to teach patients how to maintain bowel continence. Bowel control is a sensitive and embarrassing patient problem, and nurses can be instrumental in teaching patients about which methods achieve the best outcome.

manual disimpaction may get the best results. Some patients also need oral laxatives and/or stool softeners (Coggrave & Norton, 2010) (see the Evidence-Based Practice box above).

Neurologic injuries that affect the brain may cause an uninhibited bowel pattern, with frequent defecation, urgency, and reports of hard stool. Patients may manage uninhibited bowel patterns through a consistent toileting schedule, a high-fiber diet, and the use of stool softeners.

In some cases, patients are not able to regain their previous level of control over their bowel function. The rehabilitation team assists in designing a bowel elimination program that accommodates the disability.

Collaborate with patients to schedule bowel elimination as close as possible to their previous routine. For example, a patient who had stools at noon every other day before the illness or injury should have the bowel program scheduled in the same way. An exception is the patient who prefers another time that best fits into his or her daily routine. If the patient is employed during the day, a time-consuming bowel elimination program in the morning may not work. The bowel protocol can then be changed to the evening when there is more time.

Bowel retraining programs for patients with neurologic problems are often designed to include a combination of

methods. Although drug therapy should not be a first choice when formulating a bowel training program, consider the need for a suppository if the patient does not re-establish defecation habits through a consistent toileting schedule, dietary modification, anal stimulation, and disimpaction.

Bisacodyl (Dulcolax), a commonly used laxative, may be prescribed either rectally or orally as part of a bowel training program. Suppositories must be placed against the bowel wall to stimulate the sacral reflex arc and promote rectal emptying. Results occur in 15 to 30 minutes. Administer the suppository when the patient expects to defecate, for example, after a meal to coincide with the gastrocolic reflex. Using the suppository every second or third day is usually effective in re-establishing defecation patterns.

Many rehabilitation patients are at high risk for constipation, especially older adults. Encourage fluids and 20 to 35 g of fiber in the diet. Teach patients to eat 2 to 3 daily servings of whole grains, legumes, and bran cereals and 5 daily servings of fruits and vegetables. Do not offer a bedpan when toileting. Instead, be sure that the patient sits upright on a bedside commode or bathroom toilet to facilitate defecation (Association of Rehabilitation Nurses [ARN], 2002).

**NCLEX EXAMINATION CHALLENGE****Physiological Integrity**

Which statement by a newly paraplegic client indicates a need for the nurse to provide further teaching about his bowel retraining?

- A. "I need to eat lots of high-fiber foods like beans and raw fruits."
- B. "I will drink at least 2 quarts of water or other liquids every day."
- C. "I'll take oral laxatives every morning so I can go every day."
- D. "I plan to exercise by lifting weights and propelling my wheelchair."

Community-Based Care

Discharge planning begins at the time of the patient's admission. If the patient is transferred from a hospital to a rehabilitation unit or long-term care facility, orient him or her to the change in routine and emphasize the importance of self-care. When the patient is admitted, a nurse, case manager, and/or OT assess his or her current living situation at home. Together with the patient and family members or significant others, they determine the adequacy of the current situation and the potential needs after discharge to home. The patient with chronic illness and disability may require home care, assistance with ADLs, nursing care, or physical or occupational therapy after discharge.

Other health care professionals may be necessary to meet the unique needs of special populations. For example, patients with brain injury may benefit from life planning—a process that examines and plans to meet lifelong needs. External case managers specializing in life planning may be part of the interdisciplinary rehabilitation team.

Home Care Management

Before the patient returns home, the nurse assesses his or her readiness for discharge from the rehabilitation facility or hospital. The home may be assessed in multiple ways.

Predischarge Assessment. Before discharge, the case manager or OT may visit the home to assess its layout and accessibility. These professionals may be employed by the health care agency or by a third-party payer, such as a health maintenance organization. Because of the stress of hospitalization, a patient with a fractured hip who is ambulating well with a walker may neglect to explain to the nurse that the bathroom in the home is accessible by stairway only. The patient may not consider it important to mention that throw rugs, which can cause falls, are scattered throughout the apartment. Fall prevention strategies in the home environment for older adults are discussed in [Chapter 3](#).

During a predischarge visit to the home, the accessibility of bathrooms, bedrooms, and kitchen is assessed. If the patient will be wheelchair dependent after discharge from the facility, home modifications may be needed, such as ramps to replace steps. Doorways should be checked for adequate width. A doorway width of 36 to 38 inches (slightly less than 1 meter [m]) is usually sufficient for a standard-size wheelchair. Obese patients require bariatric wheelchairs and furniture and therefore need a wider door opening. Any room that the patient needs to use is assessed. The bedroom should have sufficient space for the patient to maneuver transfers to and from the wheelchair and the bed, if needed. The bathroom may need a raised toilet seat to at least 17 inches (43 cm).

Space requirements depend on the patient's need to use a wheelchair, walker, or cane. In the bathroom, grab bars may

need to be installed before the patient comes home. Bathtub benches can provide support for the patient who has difficulty with mobility and, when used in combination with a handheld showerhead, can provide easily accessible bathing facilities. Assessment of the kitchen may or may not be critical, depending on whether the patient has help with cooking and preparing meals. If the patient will be cooking after discharge, the kitchen may need to be assessed for wheelchair or walker accessibility, appliance accessibility, and the need for adaptive equipment.

Leave-of-Absence Visit. A second method of assessing the patient's home is through a brief home visit, also called a *leave-of-absence (LOA) visit*, before discharge. Explain the need for the trial home visit, and assess the patient's comfort level with this idea. The patient who has been hospitalized for a lengthy period may feel intense anxiety about returning home. The nurse may allay such anxieties with careful preparation. Before the visit, the rehabilitation nurse meets with the patient and family members or significant others to set goals for the visit and to identify specific tasks to be attempted while at home. After the home visit, interview the patient to determine the success of the visit and to assess additional education or training needs before final discharge.

Going home may not be an option for everyone. Some patients may not have a support network of family members or significant others. For example, many older adults have no spouse or close friends living nearby. Children may live far away, which can make home care difficult. If no caregiver is available, the family must decide whether care can be provided in the home by an outside resource. The patient may need to be admitted to a 24-hour supervised health care setting, such as a nursing home. Continued rehabilitation services are available in most long-term care settings (skilled nursing facilities) at least 5 days a week if it is medically necessary.

Teaching for Self-Management

The OT and PT teach the patient to perform ADLs and IADLs independently. The patient's learning potential and cognitive capacity are assessed. The patient is asked to perform or direct each skill or technique independently to verify understanding. Written material explaining the steps in the procedure is provided to the patient and family members to reinforce learning and to provide support with the technique after discharge. Before distributing written material, the rehabilitation team assesses the reading level of the material and determines whether it is appropriate for the patient's reading ability and language skills.

Any chronic illness or disability necessitates changes in lifestyle and body image. Assist the patient in dealing with such changes by encouraging verbalization of feelings and emotions. A focus on existing capabilities instead of disabilities is emphasized.

The patient may fail to relate psychologically to the disability during hospitalization. For example, he or she may display anger or frustration in attempting to perform self-care routines before discharge from the rehabilitation facility. Encourage the patient to be open about such feelings and to talk about ways to prevent worries from becoming realities after discharge. If needed, refer the patient to a mental health professional to help with adjustment and coping strategies.

The LOA home visit assists the patient and family members or significant others in psychosocial preparation for discharge. It allows the experience of the home situation while being able to return to the hospital environment after a few hours. Often the patient finds new problems in the home that must be addressed before discharge. Review this information with the patient in preparation for discharge to the home.

Health Care Resources

After discharge to the home, various health care resources (e.g., physical therapy, home care nursing, vocational counseling) are available to the patient with chronic illness and disability. Assess the need for additional care and support throughout the hospitalization, and coordinate with the case manager and physician in arranging for home services. A new technology, tele-health, allows for care coordination in the home setting. Through the use of various electronic devices, a health care team member can monitor the

patient's vital signs, weight, and other assessment data via Internet.

EVALUATION: OUTCOMES

The patient and rehabilitation team evaluate the effectiveness of interdisciplinary interventions based on the common patient problems. Expected outcomes may include that the patient will:

- Reach a level of physical mobility that allows him or her to function independently with or without assistive devices
- Prevent complications of decreased physical mobility
- Perform self-care and other self-management skills independently or with minimal assistance, possibly using assistive/adaptive devices
- Have intact skin
- Establish urinary continence without infection or retention
- Have regular evacuation of stool, without constipation

KEY POINTS

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Rehabilitation is the process of learning to live with chronic and disabling conditions; the role of the rehabilitation nurse is outlined in [Table 8-1](#).
- Patients in a rehabilitation setting are managed by an interdisciplinary team of health care professionals; the patient and family are also members of the team.
- Collaborate with the rehabilitation health care team when planning and providing patient care.
- After assessing the home environment, the case manager, OT, and/or rehabilitation nurse make recommendations to the patient and family about home modifications.
- Use evidence-based safe patient handling practices when assessing and moving patients.
- The members of the interdisciplinary team teach patients transfer, bed mobility, and gait training techniques (see [Charts 8-1 and 8-2](#)).
- The patient is taught how to perform ADLs with or without using adaptive devices; encourage the patient to be as independent as possible.

Health Promotion and Maintenance

- In coordination with the PT and OT, assess the patient's ability to perform ADLs using a functional assessment process.

- Prevent complications of immobility for patients, and teach them how to prevent complications by using interventions listed in [Table 8-3](#).

Psychosocial Integrity

- Assess the patient's self-esteem and changes in body image caused by chronic or disabling health problems.
- Assess the patient's and family's response to chronic and disabling conditions, including feelings of loss and grief.
- Assist patients in coping with their loss, and assess the availability of patient support systems.

Physiological Integrity

- Assess rehabilitation patients as outlined in [Table 8-2](#).
- The Functional Independence Measure (FIM) system is one assessment tool used to assess functional ability of the patient in rehabilitation.
- Assess patients in rehabilitation for risk factors that make them likely to develop skin breakdown; interventions to prevent skin problems include repositioning and adequate nutrition.
- Prevent other problems of immobility as delineated in [Table 8-3](#).
- Patients with neurogenic bladder and bowel problems are managed by training programs; overactive (spastic or reflex) and underactive (hypotonic or flaccid) elimination problems are managed differently (see [Tables 8-5 and 8-6](#)).
- Evaluate the ability of patients to use assistive/adaptive devices to promote independence.

End-of-Life Care

Answer Key for NCLEX Examination Challenges and
Decision-Making Challenges
Audio Glossary

Key Points
Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Explain the purpose and procedure for advance directives to patients and their families.
2. Describe the importance of collaborating with members of the interdisciplinary team when caring for the dying patient and family or other caregivers.
3. Discuss the ethical and legal obligations of the nurse with regard to end-of-life care.

Psychosocial Integrity

4. Assess the patient's and family's ability to cope with the dying process.
5. Assess and plan interventions to meet the dying patient's spiritual needs.

6. Incorporate the patient's cultural practices and beliefs when providing care during the dying process and death.
7. Identify the need for providing psychosocial support to the family or other caregivers during the patient's dying process.

Physiological Integrity

8. Assess patients for signs and symptoms related to the end of life.
9. Explain how to provide evidence-based end-of-life care to the dying patient.
10. Explain best practice guidelines for performing postmortem care.

OVERVIEW OF DEATH AND DYING

Although dying is part of the normal life cycle, it is often feared as a time of pain and suffering. For the family, death of a member is a life-altering loss that can cause significant and prolonged suffering. As sad and difficult as the death may be, the experience of dying need not be physically painful for the patient or emotionally agonizing for the family. The dying process is an opportunity to change a potentially difficult situation into one that is tolerable, peaceful, and meaningful for the patient and the family left behind.

Because nurses spend more time with patients than do any other health care providers, it is the nurse who often has the greatest impact on a person's experience with death. It is the nurse who can affect the dying process to prevent a death without dignity ("bad" death) from occurring, while striving

to promote a peaceful and meaningful death ("good death"). To accomplish this, the nurse needs to have knowledge of end-of-life care, compassion, advocacy, and therapeutic communication skills.

Perception of Death in the United States

The U.S. health care system is based on the acute care model, which is focused on prevention, early detection, and cure of disease. This focus and the advances in survival rates for once deadly diseases have made it difficult for many patients and health care providers to accept death as an outcome of disease. Many view death as a failure.

These negative views have led to a major deficiency in the quality of care provided to many Americans at the end of life. In 1995, a landmark study highlighted the poor quality of dying experienced by hospitalized patients. The Study to

Understand Prognoses and Preferences for Outcomes and Risks of Treatment (SUPPORT) showed that more than 50% of a sample of 9105 hospitalized patients with a life-threatening disease had moderate to severe pain during the last days of their lives. In addition, they did not have their wishes met, even when their wishes were known.

As a result of SUPPORT, the Institute of Medicine (IOM) studied death in America. The Institute recommended that a major initiative be undertaken to improve care at the end of life with the outcome of facilitating good death. A **good death** is one that is free from avoidable distress and suffering for patients, families, and caregivers; in agreement with patients' and families' wishes; and consistent with clinical practice standards. Pain, not having one's wishes followed at the end of one's life, isolation, abandonment, and agonizing about losses associated with death are characteristics of a **bad death**. In response to this initiative, core curricula on end-of-life care were developed and implemented to educate medical and nursing students, physicians, and nurses on how to provide quality end-of-life care.

Pathophysiology of Dying

Death is defined as the cessation of integrated tissue and organ function, manifested by lack of heartbeat, absence of spontaneous respirations, or irreversible brain dysfunction. It generally occurs as a result of an illness or trauma that overwhelms the compensatory mechanisms of the body, eventually leading to cardiopulmonary failure/arrest. Direct causes of death include:

- Heart failure secondary to cardiac dysrhythmias, myocardial infarction, or cardiogenic shock
- Respiratory failure secondary to pulmonary embolism, heart failure, pneumonia, lung disease, or respiratory arrest caused by increased intracranial pressure
- Shock secondary to infection, blood loss, or organ dysfunction, which leads to lack of blood flow (i.e., perfusion) to vital organs

Inadequate perfusion to body tissues deprives cells of their source of oxygen, which leads to anaerobic metabolism with acidosis, hyperkalemia, and tissue ischemia. Dramatic changes in vital organs lead to the release of toxic metabolites and destructive enzymes, referred to as *multiple organ dysfunction syndrome (MODS)*. As illness or organ damage progresses, the syndrome occurs with renal and liver failure. Renal or liver failure can also start the dying process.

When the body is hypoxic and acidotic, a lethal dysrhythmia such as ventricular fibrillation or asystole can occur, which ultimately leads to the lack of cardiac output. Shortly after cardiac arrest, respiratory arrest occurs. When respiratory arrest occurs first, cardiac arrest follows within minutes.

Incidence of Death

Over 2 million deaths occur every year in the United States. The most common causes of death in the United States are diseases of the heart, followed by cancer (Table 9-1).

Of all people who die, only a few (<10%) die suddenly and unexpectedly. Most people die after a long period of illness (e.g., cardiac, renal, respiratory disease), with gradual deterioration until an active dying phase before the death. Most people who die are older than 65 years.

In general, about 25% of all deaths in the United States take place at home. The rest occur in hospitals or nursing

TABLE 9-1 LEADING CAUSES OF DEATH IN UNITED STATES

2. Cancer	7. Alzheimer's disease
3. Stroke	8. Influenza and pneumonia
4. Chronic obstructive pulmonary disease	9. Kidney disease
5. Accidents	10. Septicemia

homes, but exact numbers vary depending on the region of the country.

Planning for End-of-Life and Advance Directives

Most people would prefer to die at home. Providing the type of care a person prefers, including where he or she wants end-of-life care, positively affects the dying experience for both the patient and family. These preferences need to be written as legal documents called **advance directives**.

Most Americans do not have advance directives, and many health care providers do not talk with patients about their wishes for end-of-life (EOL) care until the patients are unable to make their own decisions. Recent data suggest that older adults want early discussions with their health care provider in preparation for death (Gillick, 2010).

The primary purpose of a written advance directive is to provide guidance, especially to health care professionals, regarding how to make decisions regarding life-sustaining treatment when one loses his or her decision-making ability. To have decision-making ability, a person must be able to perform three tasks:

1. Receive information (but not necessarily oriented ×4)
2. Evaluate, deliberate, and mentally manipulate information
3. Communicate a treatment preference

By definition, the comatose patient does not have decisional ability. In this case, it becomes unclear as to how health care decisions will be made, who has the authority to make them, and what the treatment should be (Perrin, 2010a).

There are two general types of **advance directives**. The first is an instructional directive, which states the type and amount of care a person would want if he or she were to become incapacitated. **Living wills** and medical directives, such as do not resuscitate (DNR) orders, are examples of instructional directives (Perrin, 2010a).

Ethics and DNR Orders

By law, health care providers must initiate cardiopulmonary resuscitation (CPR) for a person who is not breathing or is pulseless unless that person has a DNR order. Although CPR may be effective in patients with reversible illness or single organ dysfunction, patients with terminal cancer, multisystem organ failure, and renal failure rarely survive after a cardiac arrest. Therefore a DNR order may be written in advance (called a *portable DNR*) before the patient is admitted to a health care facility. For patients who want this type of advance directive, remind them to follow their state's requirements. Most states that recognize portable DNR directives require that a state-designated, original and signed

wallet DNR card (usually pink or bright-colored) be with the patient at all times. Patients may also wear a special DNR bracelet or necklace but must have the signed wallet card with them to ensure that pre-hospital providers follow the advance directive.

Unfortunately, most patients do not obtain a portable DNR. In this case, DNR orders are usually written only a day or two before the patient's death. In general, physicians do not want to have emotional and time-consuming EOL conversations in advance. However, nurses are willing to discuss DNR options with patients and their families so that they can be involved in their own EOL decisions (Morrell et al., 2008). *According to the American Nurses Association Code of Ethics, nurses have an ethical obligation to ensure that the patient, health care proxy, or surrogate has timely information about expected care outcomes to help them make the best possible decisions* (Lachman, 2010).

A major problem with DNR orders is their unclear variations, including partial DNR (e.g., cardiac DNR or Do Not Intubate) or "slow code" orders. Several authors have suggested that these orders are medically and ethically inappropriate (Venneman et al., 2008). Instead, plans of care should be established for each person at the end of life.

Another problem with DNR orders is that they can be perceived by families and significant others that they are giving permission to end a patient's life. Some experts in death and dying have suggested that the term "allowing natural death" (AND) replace DNR. This newer term better describes a clearer intent and is less emotional and threatening than DNR (Venneman et al., 2008).

Durable Power of Attorney for Health Care

The second type of advance directive is the **durable power of attorney for health care (DPOAHC)**. The DPOAHC is a legal document in which a person appoints someone else (e.g., health care proxy) to make his or her health care decisions in the event he or she loses decision-making capacity (Fig. 9-1).

Advance directives vary from state to state but are readily available through Caring Connections, an online program of the National Hospice and Palliative Care Organization (2005) (www.caringinfo.org). Anyone can complete the advance directive forms without legal consultation. A copy of each directive should be given to the primary health care provider and health care proxy. Remind the patients and health care proxy to keep the advance directive(s) in a secure place, such as a safe deposit box or fireproof box. *Remind patients that they can change their mind at any time of their lives or at end of life.*

The Patient Self-Determination Act of 1990 requires that all patients admitted to health care agencies be asked if they have written advance directives (ADs). Patients who do not have them are provided with information on the value of having an AD in place, are advised on how they might want to choose as their DPOAHC, and are given the opportunity to complete the state-required forms. Ideally, they should be completed long before a medical crisis. Be sure to find out if your patients have these documents to ensure that the health care team follows each patient's preferences at the end of life. Because of conflict of interest, direct caregivers, such as nurses and physicians, should not witness the signature of any patient who signs advance directives.

CULTURAL AWARENESS

Thomas et al. (2008) reviewed the literature on cultural preferences for advance directives. The researchers found that European Americans (whites) had a more positive attitude and more knowledge of AD than did Mexican Americans, Asian Americans, or African Americans. Possible factors influencing these differences are related to family relationships and religiosity. Non-European-American groups tend to be more family-centered and expect that family members will make the best possible decisions about the patient's death. Many also believe that God controls when and how death will occur (see the Evidence-Based Practice box on p. 110).

Desired Outcomes for End-of-Life Care

The desired outcomes for a patient near the end of life (EOL) are that the patient will have:

- Needs and preferences met
- Control of symptoms of distress
- Meaningful interactions with family
- A peaceful death

Interventions are planned to meet the physical, psychological, social, and spiritual needs of patients using an interdisciplinary approach. The coordinated, interdisciplinary care of hospice is the most successful approach to end-of-life care to date. *Although the perception of hospice is that it provides care for the dying, the major focus of hospice care is on quality of life.*

Hospice and Palliative Care

The concept of hospice in the United States resulted from a grassroots effort in response to the unmet needs of terminally ill people. As both a philosophy and a system of care, **hospice care** uses an interdisciplinary approach to assess and address the holistic needs of patients and families to facilitate quality of life and a peaceful death (Taylor, 2009). This holistic approach neither hastens nor postpones death but provides relief of symptoms. Hospice systems of care are provided in a variety of settings. They are often affiliated with home care agencies, providing services to patients at home or in a long-term care or assisted-living facility. Some communities also have hospice houses, which provide care to patients in the terminal phase of their lives.

The *Medicare Hospice Benefits* serves as a guide for hospice care in the United States. These benefits pay for hospice services for Medicare recipients who have a prognosis of 6 months or less to live and who agree to forgo curative treatment for their terminal illness. Historically, those with terminal cancer have received hospice care more than other groups.

CONSIDERATIONS FOR OLDER ADULTS

Patients with other life-limiting conditions and life expectancies of 6 months or less are also eligible for hospice, especially older adults. Examples of these conditions are end-stage heart failure, chronic obstructive pulmonary disease (COPD), and Alzheimer's disease. Assess older patients with these illnesses to determine if they would benefit from hospice care. Teach patients and their families about this valuable resource to promote comfort during the dying process.

Guidelines are available to assist health care providers and families in identifying who is entitled to hospice care under Medicare. Patients who do not qualify for Medicare may have benefits through private insurance or government programs like medical assistance programs (e.g., Medicaid).

NEW HAMPSHIRE DURABLE POWER OF ATTORNEY FOR HEALTH CARE	
INSTRUCTIONS	
PRINT YOUR NAME	I, _____, hereby appoint _____
	(name) (name of agent)
PRINT THE NAME AND ADDRESS OF YOUR AGENT	of _____ (address)
INSTRUCTION STATEMENTS	as my agent to make any and all health care decisions for me, except to the extent I state otherwise in this document or as prohibited by law. This durable power of attorney for health care shall take effect in the event I become unable to make my own health care decisions.
CIRCLE AND INITIAL THE RESPONSES THAT REFLECT YOUR WISHES	STATEMENT OF DESIRES, SPECIAL PROVISIONS, AND LIMITATIONS REGARDING HEALTH CARE DECISIONS. For your convenience in expressing your wishes, some general statements concerning the withholding or removal of life-sustaining treatment are set forth below. (Life-sustaining treatment is defined as procedures without which a person would die, such as but not limited to the following: cardiopulmonary resuscitation, mechanical respiration, kidney dialysis or the use of other external mechanical and technological devices, drugs to maintain blood pressure, blood transfusions, and antibiotics.) There is also a section that allows you to set forth specific directions for these or other matters. If you wish, you may indicate your agreement or disagreement with any of the following statements and give your agent power to act in those specific circumstances.
TERMINAL ILLNESS	1. If I become permanently incompetent to make health care decisions, and if I am also suffering from a terminal illness, I authorize my agent to direct that life-sustaining treatment be discontinued. YES NO (Circle your choice and initial beneath it.)
PERMANENTLY UNCONSCIOUS	2. Whether terminally ill or not, if I become permanently unconscious I authorize my agent to direct that life-sustaining treatment be discontinued. YES NO (Circle your choice and initial beneath it.)
ARTIFICIAL NUTRITION AND HYDRATION	3. I realize that situations could arise in which the only way to allow me to die would be to discontinue artificial feeding (artificial nutrition and hydration). In carrying out any instructions I have given above in #1 or #2 or any instructions I may write in #4 below, I authorize my agent to direct that (circle your choice of [a] or [b] and initial beside it): (a) artificial nutrition and hydration not be started or, if started, be discontinued, —OR— (b) although all other forms of life-sustaining treatment be withdrawn, artificial nutrition and hydration continue to be given to me.
ADD PERSONAL INSTRUCTIONS (IF ANY)	If you do not complete item 3, your agent will <u>not</u> have the power to direct the withdrawal of artificial nutrition and hydration. 4. Here you may include any specific desires or limitations you deem appropriate, such as when or what life-sustaining treatment you would want used or withheld, or instructions about refusing any specific types of treatment that are inconsistent with your religious beliefs or unacceptable to you for any other reason. You may leave this question blank if you desire.
ALTERNATE AGENT	(attach additional pages as necessary)
PRINT THE NAME AND ADDRESS OF YOUR ALTERNATE AGENT	In the event the person I appoint above is unable, unwilling or unavailable, or ineligible to act as my health care agent, I hereby appoint _____ of _____ (name of alternate agent) (address of alternate agent) as alternate agent.
LOCATION OF THE ORIGINAL AND COPIES	I hereby acknowledge that I have been provided with a disclosure statement explaining the effect of this document. I have read and understand the information contained in the disclosure statement.
DATE AND SIGN THE DOCUMENT HERE	The original of this document will be kept at _____ and the following persons and institutions will have signed copies: In witness, whereof, I have hereunto signed my name this _____ day of _____, 20 _____. (day) (month) (year)
WITNESSING PROCEDURE	_____ (signature)
WITNESSES MUST SIGN AND PRINT THEIR ADDRESSES	I declare that the principal appears to be of sound mind and free from duress at the time the durable power of attorney for health care is signed and that the principal has affirmed that he or she is aware of the nature of the document and is signing it freely and voluntarily.
AND A NOTARY PUBLIC OR JUSTICE OF THE PEACE MUST COMPLETE THIS SECTION	Witness: _____ Address: _____ Witness: _____ Address: _____
©2005 National Hospice and Palliative Care Organization 2006 Revised	STATE OF NEW HAMPSHIRE, COUNTY OF _____ The foregoing instrument was acknowledged before me this _____ day of _____, 20 ____, by _____. _____ Notary Public/Justice of the Peace My commission expires:

FIG. 9-1 An example of a durable power of attorney for health care (DPOAHC).

EVIDENCE-BASED PRACTICE

What Are the Common Cultural Preferences for End-of-Life Care in Developed Countries?

Thomas, R., Wilson, D.M., Justice, C., Birch, S., & Sheps, S. (2008). A literature review of preferences for end-of-life care in developed countries by individuals with different cultural affiliations and ethnicity. *Journal of Hospice and Palliative Nursing*, 10(3), 142-161.

The researchers conducted a systematic review using the QUORUM process to determine cultural differences in end-of-life (EOL) care in the United States and other developed countries. The QUORUM process requires literature searching, selection, validity assessment, data abstraction study characteristics, and quantitative data synthesis. Most of the studies selected for the article were done in the United States.

While there were numerous findings, the key cultural differences were:

- European Americans (whites) were more knowledgeable and therefore had a more positive attitude about advance directives when compared with Mexican Americans, Asian Americans, and African Americans.
- Non-European Americans tend to be more centered on family and religion. They trust that their families and/or God will make the best decisions about end-of-life care and the dying process.
- Patients of any ethnic group were more involved in making EOL decisions if they spoke English. Those who could speak English received better pain management and more comfort measures than non-English-speaking patients.
- Non-European groups were more likely to want family present during the dying process when compared with European Americans.

- African Americans and those older than 75 years in any ethnic group had less family to rely on for comfort and decision-making support.

Level of Evidence: 1

This was a systematic study of existing qualitative research to draw conclusions about trends and differences among several ethnic groups regarding their EOL preferences. These conclusions can help guide practice for the interdisciplinary team who cares for these people at EOL.

Commentary: Implications for Practice and Research

It is apparent that European Americans (whites) have more advance directives and are involved more in EOL decision making than other groups. As a result, they receive better management for their symptoms of distress. Nurses need to advocate for and educate non-white patients and their families about EOL care and decision options. If patients cannot understand English, interpreters need to be contacted and become an active part of the health care team during this time. For adults older than 75 years who may not have families or advance directives, nurses need to seek other support systems such as clergy or close friends. All patients have the right to a good death; nurses are advocates for all patients.

**DECISION-MAKING CHALLENGE****Patient-Centered Care**

A 77-year old carpenter has difficulty swallowing, weight loss, severe anorexia, and weakness. After multiple tests, he was diagnosed with amyloidosis, a terminal illness that will likely cause cardiopulmonary failure in less than a year. The patient does not want to discuss advance directives (ADs) at this time. His daughter, however, wants him to have an AD in place and asks you as the home care nurse how you feel about his decision.

1. How will you respond to the daughter at this time?
2. Is the patient a candidate for hospice at this time? Why or why not?
3. What symptoms of distress do you anticipate that this patient will likely have and why?
4. What specific needs might he have for palliative care?
5. How will you help plan his care with him?

Because hospice benefits and care generally require a prognosis of 6 months or less, its use is limited. Many people with chronic, serious illness whose prognosis may be longer than 6 months often do not have access to the support services that work so well within the hospice model. In an attempt to address this need, palliative care has evolved.

Palliative care is both a philosophy of care and an organized, structured system for delivering care for people with serious illness who may not meet hospice eligibility criteria. The desired outcome for palliative care is to prevent and relieve suffering and to support the best possible quality of life for patients and their families, regardless of the stage of the disease or the need for other therapies. For older adults, palliation also includes enhancing or supporting functional independence as they transition between levels of care.

SIGNS AND SYMPTOMS AT END OF LIFE**Overview**

As death nears, patients often have signs and symptoms of decline in physical function, manifested as weakness, anorexia, and changes in cardiovascular function, breathing patterns, and GI and genitourinary function. As death nears, peripheral circulation decreases and the patient's skin is often cold, mottled, and cyanotic. Blood pressure decreases and often is only palpable. The dying person's heart rate may increase, become irregular, gradually decrease, and stop. Changes in breathing pattern are common, with breaths becoming very shallow and rapid. Periods of apnea and **Cheyne-Stokes respirations** (apnea alternating with periods of rapid breathing) are also common. Death occurs when respirations and heartbeat stop.

Although these signs and symptoms of physical decline are often disturbing to patients and families, they generally do not cause physical discomfort to the patient. *However, symptoms of distress that cause suffering can occur in patients with cancer and non-cancer diagnoses. Pain, weakness, and breathlessness are the most common symptoms near end of life.*

CONSIDERATIONS FOR OLDER ADULTS

Older adults typically receive fewer interventions for their end-of-life symptoms when compared with younger adults. Yet they have the same symptoms that are often more severe because of physiologic changes of aging and multiple chronic illnesses. Some older adults do not report their symptoms because they expect them to be part of the terminal illness or the aging process. Collaborate with the health care team to ensure that these problems are appropriately treated at the end of life. Anticipate symptoms of distress even if older adults cannot or do not verbalize them.

CHART 9-1 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Common Physical Signs and Symptoms of Approaching Death**Coolness of Extremities**

Circulation to the extremities is decreased; the skin may become mottled or discolored.

- Cover the person with a blanket.
- Do not use an electric blanket, hot water bottle, electric heating pad, or hair dryer to warm the person.

Increased Sleeping

Metabolism is decreased.

- Spend time sitting quietly with the person.
- Do not force the person to stay awake.
- Talk to the person as you normally would, even if he or she does not respond.

Fluid and Food Decrease

Metabolic needs have decreased.

- Do not force the person to eat or drink.
- Offer small sips of liquids or ice chips at frequent intervals if the person is alert and able to swallow.
- Use moist swabs to keep the mouth and lips moist and comfortable.
- Coat the lips with lip balm.

Incontinence

The perineal muscles relax.

- Keep the perineal area clean and dry. Use disposable underpads (Chux) and disposable undergarments.
- If the person would be more comfortable, consider a Foley catheter.

Congestion and Gurgling

The person is unable to cough up secretions effectively.

- Position the patient on his or her side.
- Administer medications to decrease the production of secretions.

Breathing Pattern Change

Slowed circulation to the brain may cause the breathing pattern to become irregular, with brief periods of no breathing or shallow breathing.

- Elevate the person's head.
- Position the person on his or her side.

Disorientation

Decreased metabolism and slowed circulation to the brain may occur.

- Identify yourself whenever you communicate with the person.
- Reorient the patient as needed.
- Speak softly, clearly, and truthfully.

Restlessness

Decreased metabolism and slowed circulation to the brain may occur.

- Play soothing music, and use aromatherapy.
- Do not restrain the person.
- Massage the person's forehead.
- Reduce the number of people in the room.
- Talk quietly.
- Keep the room dimly lit.
- Keep the noise level to a minimum.
- Consider sedation if other methods do not work.

Modified from the Hospice of North Central Florida, Inc.

**PATIENT-CENTERED
COLLABORATIVE CARE****ASSESSMENT**

Obtain information about the patient's diagnosis, past medical history, and recent state of health to identify the risks for symptoms of distress at end of life. For example, people with lung cancer, heart failure, or chronic respiratory disease are at high risk for respiratory distress and dyspnea near death. Those with brain tumors are at risk for seizure activity. Patients with tumors near major arteries (e.g., head and neck cancer) are at risk for hemorrhage. Those who have been experiencing pain often continue to have pain at the end of life, which may increase, decrease, or remain at the same level of intensity.

Physical Assessment/Clinical Manifestations

Near the end of life, the patient often becomes weak and drowsy, often sleeping 23 or more hours of the day. Eventually he or she can become unresponsive. As the patient's ability to speak diminishes, it is difficult to assess his or her perception of symptoms. When caring for those who are unable to communicate their distress or needs, identify alternative ways to assess symptoms of distress. Teach family caregivers to watch closely for objective signs of discomfort (e.g., restlessness, grimacing, moaning) and identify when these symptoms occur in relation to positioning, movement, medication, or other external stimuli (Chart 9-1).

Although the patient's point of view is the most valid indicator of comfort or distress, the family's perception of symptoms is also important. Family caregivers, health care providers, and dying patients may differ in their perceptions of symptoms in terms of intensity, significance, and meaning. Whereas health care providers are often able to identify symptoms of distress, families are often more knowledgeable about the patient's habits and preferences. Incorporate all pertinent information into the plan for symptom management, and work with patients and families toward a common outcome.

Assess any symptom of distress in terms of intensity, frequency, duration, quality, exacerbating (worsening) and relieving factors, and effect on the patient's comfort when awake or asleep. A method for rating the intensity of symptoms should be used to facilitate ongoing assessments and evaluate treatment response. A rating scale of 0 to 10 is commonly used, with 0 indicating no distress and 10 indicating the worst possible distress. The intensity of the symptom before and after an intervention (e.g., medication) is documented by the nurse or the family caregiver and is used daily to evaluate the patient's overall comfort.

Psychosocial Assessment

People facing death may have coping problems, fear, and/or anxiety about their decline and/or impending death. Assess cultural considerations, values, and religious beliefs of the patient and family for their influence on the dying experience,

CHART 9-2 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Common Emotional Signs of Approaching Death**Withdrawal**

The person is preparing to “let go” from surroundings and relationships.

Vision-like Experiences

The person may talk to people you cannot see or hear and see objects and places not visible to you. These are not hallucinations or drug reactions.

- Do not deny or argue with what the person claims.
- Affirm the experience.

Letting Go

The person may become agitated or continue to perform repetitive tasks. Often this indicates that something is unresolved or is preventing

the person from letting go. As difficult as it may be to do or say, the dying person takes on a more peaceful demeanor when loved ones are able to say things such as “It’s okay to go. We’ll be all right.”

Saying Goodbye

When the person is ready to die and you are ready to let go, saying “goodbye” is important for both of you. Touching, hugging, crying, and saying “I love you,” “Thank you,” “I’m sorry,” or “I’ll miss you so much” are all natural expressions of sadness and loss. Verbalizing these sentiments can bring comfort both to the dying person and to those left behind.

Modified from the Hospice of North Central Florida, Inc.

control of symptoms, and family bereavement. Families of people near death are also likely to manifest fear, anxiety, and knowledge deficits regarding the process of death and their role in providing care.

Assess the patient and family members for their expectations regarding death and for fear and anxiety. Families may have a preconceived notion about the dying process that may or may not be realistic. Explain the common emotional signs of approaching death to the patient and family as described in [Chart 9-2](#).

CONSIDERATIONS FOR OLDER ADULTS

Some patients, especially older adults, may develop hopelessness, helplessness, depression, and/or suicidal ideation during the dying process. These feelings are not a usual part of the process or aging and should therefore be aggressively treated. Assess the behavior and mood of older adults at the end of life, and collaborate with the health care team to develop an individualized plan of care to manage these feelings. Several excellent assessment tools are available for depression screening. See [Chapter 3](#) for more information on depression screening in older adults.

INTERVENTIONS

Interventions to relieve symptoms of distress include positioning, administration of medications, and a variety of complementary and alternative therapies. When medications are used, they are often scheduled around the clock to maintain comfort and prevent reoccurrence of the symptom. The most common end-of-life symptoms are:

- Pain
- Weakness
- Breathlessness/dyspnea
- Nausea and vomiting
- Restlessness and agitation
- Seizures

Pain Management

Pain is the most distressing symptom that dying patients fear the most. Diseases such as cancer often cause tumor pain as a result of the infiltration of cancer cells into organs, nerves, and bones. Other causes of pain in dying patients include

osteoarthritis, muscle spasms, and stiff joints secondary to immobility.

Patients who have had their pain controlled with long-acting opioids continue their scheduled doses of opioids to prevent pain reoccurrence. Depending on the brand of long-acting opioid, oral capsules may be given rectally (same dose and same capsule) when swallowing is impaired. Increases in pain require immediate-relief analgesics (e.g., morphine sulfate immediate-release). Morphine sulfate elixir can be given sublingually, via the buccal mucosa, or rectally. It is quick-acting, effective, and safe to administer, even to comatose patients.

CONSIDERATIONS FOR OLDER ADULTS

Research shows that pain relief is the priority need of older adults receiving palliative care. But, pain is often underreported and under-treated (Wijk & Grimby, 2008). Opioids should not be withheld from older adults. Instead, reduce starting doses, make dose increases slowly, and monitor for changes in mental status or excessive sedation.

Some experts in palliative care recommend discontinuing routine doses of opioids such as morphine when patients become oliguric or anuric. The rationale is to decrease the risk for delirium that may occur as the result of a failing kidney’s inability to excrete morphine metabolites from the body. This practice is not the standard of care, and the nurse should never discontinue administration of opioids without consulting with experts on end-of-life care.

For patients with known renal failure, fentanyl citrate is a safer opioid alternative to morphine because it lacks active metabolites. [Chapter 5](#) describes in detail the management of chronic malignant and nonmalignant pain.

Complementary and Alternative Therapies. Nonpharmacologic interventions are often integrated into the pain management plan. Some common approaches are presented here, as well as in [Chapters 2 and 5](#).

Massage has been shown to decrease pain in people with cancer and is one of the most popular complementary services used for patients at end of life. A qualitative study by Beck et al. (2009) found that daily massage also enhances

dignity and helps patients find inner peace when incorporated into the palliative plan of care. This technique involves manipulating the patient's muscles and soft tissue, which improves circulation and promotes relaxation. Patients who are severely weak, arthritic, or advanced age may not tolerate extensive massages but, rather, may benefit from a short treatment to sites of their choice. In working with patients with cancer, use light pressure and avoid deep or intense pressure. Massage should not be done over the site of tissue damage (e.g., open wounds, tissue undergoing radiation therapy), in patients with bleeding disorders, and in those who are uncomfortable with touch.

Music therapy is another complementary therapy used by people near end of life that has been shown to decrease pain. It is thought to decrease pain by promoting relaxation. Select music based on patient preferences.

Therapeutic Touch, which involves moving one's hands through the patient's energy field, has also been shown to relieve pain. Reiki therapy is another type of energy therapy being evaluated for its role in pain and symptom management. Use of Reiki requires a Reiki practitioner who is trained in the method.

Aromatherapy can be used in conjunction with other treatments to relieve pain near end of life. It is thought to decrease pain by promoting relaxation and reducing anxiety. Lavender, capsaicin, bergamot, chamomile, rose, ginger, rosemary, lemongrass, sage, and camphor have been used in palliative care. Some aromas increase nausea and/or vomiting.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

A client with terminal metastatic bone cancer is receiving palliative care including pain management. What interventions are the most appropriate for the nurse to implement for this client? **Select all that apply.**

- A. Provide pain medication when the client or family requests it.
- B. Use music therapy to help the client relax and decrease anxiety.
- C. Provide soft massage to help the client maintain his dignity.
- D. Help the client assume the best position of comfort.
- E. Use lavender as aromatherapy to help relax the client.

Weakness Management

Patients commonly experience weakness and fatigue as death nears. Weakness combined with decreased neurologic function may impair the ability to swallow (dysphagia). Once the patient is unable to swallow, oral intake should stop. Teach families about the risk for aspiration, and reassure them that anorexia is normal at this stage. Giving fluid or food can actually lead to discomfort. Families may have great difficulty accepting that their loved ones are not being fed and may request that IV fluids be started.

With great sensitivity, reinforce that stopping food and liquid intake and dehydration are natural processes. Inform families that giving fluids can actually increase discomfort in a person with multisystem slowdown. Discomfort from fluid replacement could lead to respiratory secretions (and distress), increased GI secretions, nausea, vomiting, edema, and ascites. Most experts believe that dehydration in the last hours of life (i.e., terminal dehydration) does not cause distress and may stimulate endorphin release that promotes a patient's sense of well-being. One side effect of dehydration that may

be uncomfortable is dry lips and mouth. Apply an emollient to soften the lips, and moisten the mouth and lips with applicators to help prevent and/or relieve this symptom.

Dysphagia near death presents a problem for oral drug therapy. Although some pills may be crushed, drugs such as sustained-release capsules should not be taken apart. Reassess the need for each drug. Collaborate with the prescriber about discontinuing drugs that are not needed to control pain, dyspnea, agitation, nausea, vomiting, cardiac workload, or seizures. In collaboration with a pharmacist experienced in palliative care, identify alternative routes and/or alternative medications to maintain control of symptoms. Choose the least invasive route such as oral, buccal mucosa (inside cheek), transdermal, or rectal. Many oral drugs can be given rectally. The subcutaneous or IV routes are used only if necessary, and the IM route is almost never used at the end of life. These methods are invasive and painful and can cause infection.

Breathlessness/Dyspnea Management

Dyspnea is a subjective experience in which the patient has an uncomfortable feeling of breathlessness, often described as terrifying. It is a common symptom of distress near the end of life, especially among older adults because of decreased oxygen reserves from aging. Patients, families, and health care providers consider it the major cause of suffering at end of life. Dyspnea can be:

- Directly related to the primary diagnosis (e.g., lung cancer, breast cancer, coronary artery disease)
- Secondary to the primary diagnosis (e.g., pleural effusion, metastasis to the lung or pleura)
- Related to treatment of the primary disease (e.g., heart failure caused by chemotherapy, constrictive pericarditis caused by radiation therapy, anemia related to chemotherapy)
- Unrelated to the primary disease (e.g., pneumonia)

Depending on the cause, the pathophysiology of dyspnea can involve:

- Obstructive, restrictive, or vascular disturbances in the airways with tumor or nodal involvement
- Pulmonary congestion secondary to fluid overload and/or cardiac dysfunction
- Bronchoconstriction and bronchospasm as seen with respiratory infection, chronic obstructive pulmonary disease (COPD), or airway blockage by a tumor
- Decreased hemoglobin-carrying capacity, as with anemia
- Hyperventilation secondary to neuromuscular disease, with limited movement of the diaphragm

NURSING SAFETY PRIORITY

Action Alert

Perform a thorough assessment of the patient's dyspnea. Include onset, severity (e.g., on a 1 to 10 scale), precipitating factors, and quality. Precipitating factors may include time of day, position, anxiety, or emotional distress. Also, ask about other symptoms that occur when dyspnea worsens, such as pain, cough, fever, or dizziness. This information helps with planning an individualized patient plan of care.

Pharmacologic interventions should begin early in the course of dyspnea near death. Nonpharmacologic interventions can be used in conjunction with, but not in place of, drug therapy.

Opioids such as morphine sulfate are the standard treatment for dyspnea near death. They work by (1) altering the perception of air hunger, reducing anxiety and associated oxygen consumption and (2) reducing pulmonary congestion by dilating pulmonary blood vessels. The optimum dose of morphine for breathlessness is generally less than that for pain relief. Patients who have not been receiving opioids are given starting doses of 5 to 6 mg (or less for a frail person) orally every 4 hours during the day and 10 mg at bedtime. If dyspnea is limited to activity, give morphine before the activity up to every 2 hours. Those who are taking morphine or other opioids for pain may need higher doses for breathlessness, at times up to 50% more than their usual dose. If IV access is available, health care providers may prescribe 1 to 2 mg of morphine to be given every 5 to 10 minutes until dyspnea is relieved.

Oxygen therapy for dyspnea near death has not been established as a standard of care for all patients. However, those who do not respond promptly to morphine or other drugs should be tried on oxygen (2 to 6 L by nasal cannula) to assess its effect. Patients often feel more comfortable when the oxygen saturation is greater than 90%. If possible, provide oxygen by nasal cannula (NC) because masks can be frightening. If oxygen is not effective, discontinue it.

Bronchodilators, such as albuterol (Proventil) or ipratropium bromide (Atrovent, Apo-Ipratent 🍀) via a metered dose inhaler (MDI) or nebulizer, may be given for symptoms of bronchospasm (heard as wheezes). *Corticosteroids*, such as prednisone (Deltasone, Winpred 🍀), may also be given for bronchospasm and inflammatory problems within and outside the lung. Superior vena cava syndrome and cancer-related lymphangitis causing dyspnea may also respond to corticosteroids.

People who have fluid overload with dyspnea, crackles on auscultation, peripheral edema, and other signs of heart failure may be given a *diuretic* such as furosemide (Lasix, Uritol 🍀) to decrease blood volume, reduce vascular congestion, and reduce the workload of the heart. Furosemide can be administered by mouth, IV, subcutaneously, or IM. IV push administration, which is effective within minutes, may be preferred for heart failure and pulmonary edema to promote comfortable breathing.

Antibiotics may be indicated for dyspnea from a respiratory infection. A thorough workup for a respiratory infection is not appropriate when death is imminent. However, if signs or symptoms of a respiratory infection occur along with the dyspnea, a trial of an appropriate antibiotic may be considered to make the patient comfortable.

Secretions in the respiratory tract and oral cavity may contribute to dyspnea near death. Loud, wet respirations (referred to as **death rattle**) are disturbing to family and caregivers even when they do not seem to cause dyspnea or respiratory distress. Reposition the patient onto one side to reduce gurgling, and place a small towel under his or her mouth to collect secretions. *Anticholinergics*, such as atropine ophthalmic solution 1% every 4 hours as needed or hyoscyamine (Levsin) every 6 hours are commonly given orally or sublingually to dry up secretions. Scopolamine may also be given transdermally or subcutaneously to reduce secretion production. Oropharyngeal suctioning is not recommended for loud secretions in the bronchi or oropharynx because it is not effective and may only agitate the patient.

Fear and anxiety may be components of respiratory distress at end of life. For this reason, benzodiazepines are commonly given when morphine does not fully control the person's dyspnea. Low-dose lorazepam (Ativan) is administered orally, sublingually, or IV every 4 hours as needed or around the clock.

Nonpharmacologic interventions include:

- Circulating cool air (e.g., via air conditioner and fan)
- Applying wet cloths on the patient's face
- Positioning the patient with the head of the bed up either in a hospital bed or a reclining chair to increase chest expansion
- Encouraging imagery and deep breathing

Insertion of a urinary (Foley) catheter to avoid the need for exertion with voiding may be a comfort measure if the patient or family agrees.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

The nurse is caring for a client who has severe dyspnea because of end-stage chronic obstructive pulmonary disease. Which interventions are the most appropriate to help improve his breathing? **Select all that apply.**

- A. Give the client humidified high-dose oxygen via facemask.
- B. Administer morphine sulfate on an around-the-clock schedule.
- C. Teach the client and family to keep him in a sitting position.
- D. Use a large electric fan to circulate the air.
- E. Keep the room temperature warm to prevent respiratory infection.
- F. Teach the client and family to use bronchodilators as prescribed.

Nausea and Vomiting Management

Although not as common a problem as pain or dyspnea, nausea and vomiting occurs frequently among terminally ill patients during the last week of life. It is particularly common in patients with acquired immune deficiency syndrome (AIDS) or breast, stomach, or gynecologic cancers.

Other causes of nausea and vomiting at the end of life include:

- Uremia (increased serum urea nitrogen)
- Hypercalcemia
- Increased intracranial pressure
- Constipation or impaction
- Bowel obstruction

If constipation is identified as the cause, give the patient a biphosphate enema (e.g., Fleet) to release stool quickly. If stool in the rectum cannot be evacuated, a mineral oil enema followed by gentle disimpaction may relieve the patient's distress. Nausea and vomiting related to other causes can be controlled by one or more antiemetic agents such as prochlorperazine (Compazine, Stemetil 🍀), dexamethasone (Decadron, Deronil 🍀, Dexasone 🍀), or metoclopramide (Reglan, Maxeran 🍀). Based on a patient's response, one or more of these drugs may be combined and compounded into rectal suppositories, gels, or oral troches. In addition to providing medications, be sure to remove sources of odors and keep the room temperature at a level that the patient desires.

Complementary and Alternative Therapies. Aromatherapy using peppermint and rosewood may help relieve nausea for some patients. For other patients, any aroma worsens

their nausea. Aromatherapy using chamomile, camphor, fennel, lavender, peppermint, and rose may reduce or relieve vomiting.

Restlessness and Agitation Management

Agitation at the end of life first requires assessing for pain or urinary retention, constipation, or another reversible cause. If constipation is ruled out as the cause and if analgesia and catheterization do not relieve restlessness, another type of medication is administered. The type of medication chosen is based on the presence or absence of delirium. Delirium is a neuropsychiatric syndrome manifested by changes in level of consciousness, attention, and cognition, with an abrupt onset and a fluctuating course. It is very common in the last weeks of life. *Hypoactive (quiet)* delirium is probably not uncomfortable for patients. *Agitated (noisy)* delirium with emotional and behavioral symptoms (e.g., yelling, hallucinations) can be uncomfortable, especially for family.

Although a diagnostic workup is not appropriate when either type occurs near end of life, health care providers consider possible causes such as the adverse effects of opioids, benzodiazepines, anticholinergics, or steroids. In this case, these agents may be decreased or discontinued, particularly if the drugs were recently started. A low dose of haloperidol (Haldol, Peridol ) , an antipsychotic (also called a *neuroleptic*) drug, is the first-line therapy for terminal agitated delirium. Other antipsychotics may be used if this drug is not effective in managing behaviors. *Do not give the patient more than one antipsychotic drug at a time because of the risk for adverse drug events (ADEs).*

! NURSING SAFETY PRIORITY

Drug Alert

In a patient with anxiety without signs of delirium, a benzodiazepine such as lorazepam may be tried for agitation or severe restlessness. Place lorazepam (Ativan, Apo-Lorazepam ) elixir or a tablet (0.5-1 mg) dissolved in 0.5 mL of water against the buccal mucosa. Most patients become more relaxed with 2 to 10 mg in 24 hours. To prevent agitation, give the drug every 3 to 4 hours around the clock. Development of increased agitation after receiving benzodiazepine could represent a paradoxical reaction—the opposite action from what is expected. If paradoxical agitation occurs, discontinue the lorazepam immediately and notify the physician. A neuroleptic such as haloperidol (0.5-2 mg IV, subcutaneously, or rectally) is usually given instead.

Complementary and Alternative Therapies. Music therapy may produce relaxation by quieting the mind and promoting a patient's restful state. Aromatherapy with chamomile may also help overcome anxiety, anger, tension, stress, and insomnia in dying patients.

Seizure Management

Seizures are not common at end of life but may occur with brain tumors, advanced AIDS, and pre-existing seizure disorders. Around-the-clock drug therapy is needed to maintain a high seizure threshold for patients who can no longer swallow antiepileptic drugs (AEDs) and are at risk for seizures. Benzodiazepines, such as diazepam (Valium) and lorazepam (Ativan), are the drugs of choice. For home use, rectal diazepam gel or sublingual lorazepam oral solution (2 mg/mL) is preferred. As a second choice, barbiturates such as phenobarbital may be given rectally, IV, or IM.

Management of the Refractory Symptoms of Distress

Patients receiving opioids for pain or dyspnea and other drugs such as antiemetics or antianxiety agents may experience mild sedation as a side effect to therapy. Depending on the patient and how soon death is expected, this side effect may decrease with time. What is important to understand is that drug therapy for symptoms of distress at end of life is guided by protocols, using medications that are safe, that are used with the intent of alleviating suffering, and that do not cause severe sedation or hasten death. *There is no evidence that administering medications for symptoms of distress using established protocols hastens deaths. The ethical responsibility of the nurse in caring for patients near death is to follow guidelines for drug use to manage symptoms and to facilitate prompt and effective symptom management until death.*

A small percentage of patients have refractory symptoms of distress that do not respond to treatment near the end of life. These patients may be candidates for **palliative sedation**—a care management approach involving the administration of drugs such as benzodiazepines (e.g., midazolam [Versed]), neuroleptics, barbiturates, or anesthetic agents (e.g., propofol [Diprivan]) for the purpose of “lowering of patient consciousness.” *The purpose of palliative sedation is to control symptoms of distress, not hasten the patient's death. The intent to promote comfort and not hasten death makes it different from euthanasia (discussed later in the chapter).*

Because of its promotion of deep sedation, palliative sedation has been controversial. However, with expert consultation, its use is supported by a consensus of experts in palliative care as a comfort therapy of last resort (Kirk et al., 2010).

Psychosocial Management

The personal experience of dying or of losing a loved one through death can be extremely difficult. But unexpected deaths, particularly in young people, tend to be most traumatic for families. When a person has a chronic life-threatening disease, he or she and the family often have some knowledge of the expected outcome. This knowledge and the gift of time may provide patients and families the opportunity to make their wishes known and develop plans of care consistent with their values and needs.

Whereas death is the termination of life, dying is a process. People facing death may demonstrate emotional signs and symptoms of their response to the dying process through behaviors that equate to saying goodbye or through actual withdrawal. Some patients attempt to make families feel better by reassuring them that everything will be fine. Teach families that such behaviors are normal to the process of dying (see [Chart 9-2](#)).

Assisting Patients During the Grieving Process. **Grief** is the emotional feeling related to the perception of the loss. **Mourning** is the outward social expression of the loss. Interventions to assist patients and families in grieving and mourning are based on their cultural beliefs, values, and practices. Some patients and their families express their grief openly and loudly, whereas others are more quiet and reserved. [Table 9-2](#) lists basic beliefs regarding death, dying, and afterlife for some of the major religions.

Nursing interventions are aimed at providing appropriate emotional support to allow patients and their families to verbalize their fears and concerns. Support includes keeping the patient and family involved in health care decisions and

TABLE 9-2 BASIC BELIEFS REGARDING CARE AT END OF LIFE AND DEATH RITUALS FOR SELECTED RELIGIONS**Christianity**

- Eternal life (Heaven) is a gift that is granted to all who accept salvation through Jesus Christ.
- Jesus Christ is believed to be the Son of God, both human and divine and a mediator between God and sinful human beings.
- There are many Christian denominations, which have variations in beliefs regarding medical care near end of life.
- Funerals tend to be highly involved ceremonies with defined rituals; family, friends, and acquaintances of the deceased make an effort to attend.
- Roman Catholics are encouraged to receive Sacrament of the Sick, administered by a priest at any point during an illness. Catholics no longer have Last Rites (Extreme Unction) given at the time of death.
- People may be baptized as Roman Catholics in an emergency situation (e.g., person is dying) by a layperson. Otherwise, they are baptized by a priest.
- Catholic Moral Tradition acknowledges that, in some situations, forgoing of treatment would be morally permissible (Supportive Care Coalition, 2008).

Judaism

- There is a strong belief in the sacredness of life, one God (YHWH), and the importance of community (i.e., belonging to a group).
- God and man are bound together by a covenant.
- Religious beliefs vary. It is not required that all Jewish believers accept all tenets of the Torah (the Five Books of Moses).
- If the person is suffering pain, we have an obligation to alleviate it, even if it contradicts achieving the maximum life span for this person. Torah law sanctions avoiding invasive procedures that do not offer hope of a cure.

- There is a belief that the soul does not completely leave this world until after burial.
- The body, which was the vessel and vehicle to the soul, deserves our reverence and respect.
- The body should not be left unattended until the funeral, which should take place as soon as possible (preferably within 24 hours).
- Autopsies should not be performed, except under special circumstances.
- The body should not be embalmed, displayed, or cremated.
- A 7-day mourning period, called *Shiva*, follows the person's death for the immediate next of kin.

Islam (Muslim)

- Based on belief in one God Allah and his prophet Muhammad. Qur'an is the scripture of Islam, composed of Muhammad's revelations of the Word of God (Allah).
- Life is meant to be a test for the preparation of everlasting life in the hereafter.
- God has prescribed an appointed time of death for everyone.
- Qur'an encourages humans to seek treatment and not to refuse treatment. Belief is that only Allah cures, but that Allah cures through the work of humans.
- Dying person of Muslim faith may wish to lie facing Mecca.
- Upon death, the eyelids are to be closed and the body should be covered. Before moving and handling the body, contact someone from the person's mosque to perform rituals of bathing and wrapping body in cloth.
- Preparation for burial takes place as soon as possible after death.
- Death is seen as the transition to the other side, with Islam being the vehicle that will take one there.

CHART 9-3 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE***Psychosocial Interventions for Care of the Dying Patient and the Family***

- Offer physical and emotional support by “being with” the patient.
- Respect cultural preferences.
- Be realistic.
- Encourage reminiscence.
- Promote spirituality.
- Foster hope.
- Avoid explanations of the loss.
- Communicate with the patient.
- Provide referrals to bereavement specialists.
- Teach about the physical signs of death (see [Chart 9-1](#)).
- Ensure that the patient is receiving palliative care, with an emphasis on symptom management.

emphasizing that the patient will remain as comfortable as possible until death. Interventions for providing psychosocial support are summarized in [Chart 9-3](#).

Intervene with those grieving an impending death by “being with” as opposed to “being there.” “Being with” implies that you are physically and psychologically with the grieving patient, empathizing to provide emotional support. Listening and acknowledging the legitimacy of the patient's and/or family's pain are often more therapeutic than speaking; this concept is often referred to as **presence**. Nurses facilitate the expression of grief by giving the person who is mourning permission to express himself or herself. Your manner and words show that these expressions of grief are acceptable and expected. An example of therapeutic communication might be “This must be very difficult for you” or “I'm sorry this is happening.”

A patient's or family member's pain of loss should not be minimized. Avoid trite assurances such as “Things will be fine.

Don't cry,” “Don't be upset. She wouldn't want it that way,” or “In a year you will have forgotten.” Such comments can be barriers to demonstrating care and concern. Accept whatever the grieving person says about the situation, and remain present, be ready to listen attentively, and guide gently. In this way, you can help the bereaved prepare for the necessary reminiscence and integration of the loss.

Storytelling through reminiscence and life review can be an important activity for patients who are dying. **Life review** is a structured process of reflecting on one's life, which is often facilitated by an interviewer. **Reminiscence** is the process of randomly reflecting on memories of events in one's life. The benefits of storytelling through either method provide the ability to attain perspective and enhance meaning. Suggest that the patient and family record autobiographic stories (print or video), write memories in a journal, or develop a scrapbook. Young dying parents often write letters for their children to read when they are older. If the patient does not

have enough energy for these activities, familiar objects such as photographs and favorite jewelry can be used to spark ideas for stories.

Meeting Spiritual Needs. **Spirituality** is whatever or whoever gives ultimate meaning and purpose in one's life that invites particular ways of being in the world in relation to others, oneself, and the universe. **Religion** is affiliation or membership in a particular faith community in which members share a set of beliefs, rituals, morals, and sometimes a health code, centered on a defined higher power, most frequently referred to as God. For some patients, spirituality and religion can help cope with the thought of death, contributing to quality of life during the dying process. Perform a spiritual assessment to identify the patient's spiritual needs and to facilitate open expression of his or her beliefs and needs. A spiritual assessment could start with questions such as "What is important to you?" or "What gives you meaning or purpose in your life?"

CULTURAL AWARENESS

When assessing the spiritual needs of the dying patient, consider end-of-life preferences based on ethnic beliefs and practices. For example, the medicine wheel represents the spiritual journey to find one's own path for indigenous people in many countries, including American Indians (e.g., Cherokee, Navajo, Lakota) and Aboriginal people (e.g., Inuit, First Nations) in Canada and Alaska (also known as *Alaska Natives*). The medicine wheel helps people in these groups maintain balance and harmony within four life dimensions (Clarke & Holtzlander, 2010) (Fig. 9-2). Depending on specific tribal practices and beliefs, the dimensions may be represented by colors, seasons, or directions. Patients in these groups experience life reviews based on the dimensions of the medicine wheel to have a meaningful death.

As part of the dying process, certain tribal ceremonies must also take place for patients to have a peaceful transition into the Spirit World and experience a "good death." One special ceremony involves smudging: Selected tribal medicines are burned, and the smoke is passed over the patient's body to cleanse it.

Be aware that supporting patients and their families within their cultural framework is essential as part of the dying process for all patients. Respect all practices, and allow for privacy during ceremonies and ritual practices.

Some patients do not identify with any religious or spiritual group; some patients are atheist or agnostic. Others who have been alienated from their religious or spiritual community may have difficulty finding meaning in their suffering, or approaching death causes spiritual distress. Possible causes include guilt, regrets, lack of meaning, poor relationships, and fear of the unknown. Acknowledge the patient's spiritual pain, if present, and encourage verbalization. Use a family tree to discuss relationships, fears, hopes, and unfinished business. Explore issues related to forgiveness for possible resolution if needed.

Hope involves picturing a reality that is not yet present and imagining what a situation might be like. This image sets the direction for patients and their families to provide purpose in life and to help them find the strength to go forward, even in the darkest times. *Foster hope for patients and their families by listening and caring, but remain realistic.*

Do not try to explain the loss in philosophic or religious terms. Statements such as "Everything happens for the best" or "God sends us only as much as we can bear" are not helpful when the bereaved person has yet to express feelings of anguish or

FIG. 9-2 An example of a medicine wheel used by indigenous people to provide harmony and balance in life and transition into the spirit world after death.

anger. Telling someone too soon that he or she has other children to rely on or that other family members need them does not diminish the intensity of the grief. In fact, doing so can create feelings of anger and resentment toward the nurse because it reflects insensitivity to the patient's emotional pain. "Being with" remains important as the weeks or months pass and the funeral crisis supports often disappear. The out-of-town relatives leave, and friends and local relatives resume their own lives. Consider contacting family members after the death to allow them the opportunity to voice their perceptions of the experience. Family caregivers who assumed the role of symptom manager in the home often welcome the opportunity to discuss their experience.

Patients near death are often obtunded or withdrawn from the external environment. However, it is believed that their sense of hearing remains intact until death. *Conversation in the room and near the patient should occur as if he or she is alert.* Encourage caregivers to talk softly to the patient and to touch and gently stroke the skin, if culturally acceptable. Although the dying person may not respond, these actions foster a sense of communication between the patient and the caregiver.

Assisting with Survivor Bereavement. **Bereavement** includes grief and mourning—the inner feelings and outward reactions of survivors. *Inform the patient and family about bereavement counselors who can assist them to cope both before and after the death.* Bereavement counselors are knowledgeable about the grieving process and can be accessed through hospice agencies. Any nurse caring for people who are dying or have died should know how to access this resource.

Participation in bereavement support groups by people who are grieving a person's pending or past death facilitates the grieving process. Being a part of a support group can help

people discover that others have suffered through an experience just as devastating as their own. This discovery makes them more likely to share their feelings with others and work toward some resolution of the experience.

Although emotionally challenging, witnessing the death of a loved one may help facilitate the family to accept death. Witnessing how ill a person is makes the event real and enhances an understanding of how disease affects bodily function and decline. If death is anticipated, use nontechnical language to give the patient and family information about the signs of death. Describe the physical signs in detail—realistic enough to be unmistakable yet not so graphic as to alarm the listeners. [Chart 9-1](#) describes the common signs and symptoms of approaching death, and [Chart 9-2](#) describes the common emotional signs of impending death.

Family and friends who are anticipating the death of a loved one often fear that dying is about pain and suffering. *Reassure families that patients whose symptoms are being well managed before death will likely die comfortably. Patients in health care settings will be monitored closely for any sign or symptom of distress, and appropriate interventions will be administered as needed.* Hospice nurses review signs and symptoms of distress and its treatment with families who are providing direct care in the home, and contact them daily to offer assistance with symptom management. The home care or hospice nurse also emphasizes that he or she is available by phone or e-mail 24 hours a day.

Most people who choose hospice care prefer the home to other environments during the final episodes of illness. Although there are exceptions, being surrounded by familiar people and things, having ready access to friends and family (including pets), and being free from institutional restrictions make the home setting more comfortable and give the person and family more control. If patients are not able to stay at home until death, provide information about the nearest inpatient hospice unit or facility. In these settings, families are allowed to remain with patients. Interdisciplinary hospice team meetings are routinely conducted in both home hospice and inpatient hospice agencies to review the patient's plan of care.

It is not always possible to predict the final phase of the terminal process or the development of symptoms of distress. To address this problem, many hospices have arranged for pharmacies to supply patients and their families with "symptom relief kits." These kits provide a limited amount of commonly used drugs that are effective in treating symptoms near death ([Chart 9-4](#)).

POSTMORTEM CARE

Nurses or family members usually recognize a person has died when they stop breathing. [Chart 9-5](#) lists other physical manifestations of death. If the death was in the home, and expected, emergency assistance is not notified. If the person was a patient in a hospice program, the family calls hospice. If a death is unexpected or suspicious, the medical examiner is notified. Otherwise, the nurse or physician performs the pronouncement and completes a death certificate.

Ask the family or other caregivers if they would like to spend time with the patient to assist them in coping with what has happened and say their good-byes. Even if the death has been anticipated, no one knows how he or she will feel

CHART 9-4 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Symptom Relief Kit for Patients in Home Hospice

- For unrelieved pain: Morphine solution (20 mg/1 mL solution) 0.25 to 0.5 mL orally or sublingually every 2 to 3 hours as needed.
- For unrelieved dyspnea: Morphine solution (20 mg/1 mL solution) 0.25 to 0.5 mL orally or sublingually every 2 hours as needed.
- For nausea or vomiting: Prochlorperazine 25-mg suppository rectally or 10-mg tablet orally every 6 hours as needed.
- For severe agitation and restlessness:
 - Determine if patient is in pain; treat accordingly.
 - Determine if patient is experiencing urinary retention; insert straight or Foley catheter.
 - Haloperidol 0.5 to 1 mg orally or sublingually every 4 hours.
 - Lorazepam 0.5 mg to 1 mg elixir or tablet dissolved in 0.5 mL water, administered against buccal mucosa every 4 hours to keep patient comfortable. If patient becomes more agitated after lorazepam, discontinue and contact hospice.
- For oral secretions or loud, wet respirations:
 - Atropine sulfate ophthalmic drops 1%, (2 drops orally or sublingually) every 4 hours as needed; or hyoscyamine (Levsin) (0.125-0.25 mg every 6 hours).
 - Scopolamine 1 to 3 transdermal patches every 72 hours.
- For unrelieved pain, dyspnea, nausea, vomiting, agitation, or secretions, call hospice.

CHART 9-5 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Signs That Death Has Occurred

- Breathing stops.
- Heart stops beating.
- Pupils become fixed and dilated.
- Body color becomes pale and waxy.
- Body temperature drops.
- Muscles and sphincters relax.
- Urine and stool may be released.
- Eyes may remain open, and there is no blinking.
- The jaw may fall open.
- Observers may hear trickling of fluids internally.

until it occurs. It may take hours to days to weeks or months for each person to realize the full effect of the event. Some family members may find it therapeutic to bathe and prepare the person's body for transfer to the funeral home or the hospital morgue. Offer families this opportunity if it is culturally acceptable.

Before preparing the body for transfer, ask the physician whether an autopsy will be ordered. When the death is expected, an autopsy is not likely. But when the physician or family members do not know the cause of death, an autopsy may be performed.

After the family or significant others view the body, follow agency procedure for preparing the patient for transfer to either the morgue or a funeral home. In the hospital, a postmortem kit is generally used with a shroud and identification tags. [Chart 9-6](#) describes best practice guidelines for postmortem care.

CHART 9-6 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Postmortem Care

- Provide all care with respect, to communicate that the person was important and valued.
- Ask the family or significant others if they wish to help wash the patient or comb his or her hair.
- If no autopsy is planned, remove or cut all tubes and lines according to agency policy.
- Close the patient's eyes.
- Insert dentures if the patient wore them.
- Straighten the patient, and lower the bed to a flat position.
- Place a pillow under the patient's head.
- Wash the patient as needed; comb and arrange the patient's hair.
- Place waterproof pads under the patient's hips and around the perineum to absorb any excrement.
- Clean the patient's room or unit.
- Allow the family or significant others to see the patient in private and to perform any religious or cultural customs they wish (e.g., prayer).
- Assess that all who need to see the patient have done so, before transferring to the funeral home or morgue.
- Notify the hospital chaplain or appropriate religious leader if requested by the family or significant others.
- Ensure that the nurse or physician has completed and signed the death certificate.
- Prepare the patient for transfer to either a morgue or funeral home; wrap the patient in a shroud and attach identification tags per agency policy.

EUTHANASIA

Nurses are usually in the best and most immediate position to discuss end-of-life issues. This includes assisting in the decision-making process regarding immediate or future needs. To do this, nurses must be knowledgeable about terminology and ethical issues related to death and dying (Table 9-3).

Much confusion exists regarding the concept of euthanasia. **Withdrawing or withholding life-sustaining therapy**, formerly called **passive euthanasia**, involves discontinuing one or more therapies that might prolong the life of a person who cannot be cured by the therapy. Another phrase sometimes used is “letting the person die naturally” or “allowing natural death (AND),” as discussed earlier in this chapter. *In this situation, the withdrawal of the intervention does not*

TABLE 9-3 DEFINITIONS OF ETHICAL CONCEPTS RELATED TO ISSUES AT END OF LIFE

Withdrawing or withholding life-sustaining therapy (formerly called **passive euthanasia**) An act of omission (e.g., withholding or withdrawing treatment) that might prolong the life of a person who cannot be cured by the treatment. In this situation, the withdrawal of the intervention does not directly cause the patient's death.

Principle of double effect Involves taking an action intended to have a good effect, which also has a known harmful effect. This is not active euthanasia.

Voluntary active euthanasia An act by which the causative agent or treatment in the death of a patient is administered directly by another.

Involuntary active euthanasia The action to end the patient's life is taken without the patient's consent.

Physician-assisted suicide A practice whereby a physician provides a means (e.g., medication) to a patient with the knowledge that the patient will use the means to commit suicide.

directly cause the patient's death. The progression of the patient's disease or poor health status is the cause of death. Professional organizations (e.g., American Nurses Association, American Medical Association) and religious communities (e.g., the Catholic church) support the right of patients and their surrogate decision makers to refuse or stop treatment (e.g., mechanical ventilation, antibiotics, IV fluids) when patients are close to death and interventions are considered medically futile and/or capable of causing harm. The U.S. court system also supports withdrawal of aggressive treatment and the rights of surrogate decision makers to refuse or stop treatment.

By contrast, **active euthanasia** requires that health care providers take action (e.g., give medication or treatment) that purposefully and directly causes the patient's death. *Active euthanasia is not supported by most professional organizations, including the American Nurses Association. In the states of Oregon and Washington, physician-assisted suicide is legal in certain situations. Nurses should not be involved in active euthanasia or physician-assisted euthanasia. They do, however, play a major role in end-of-life care by advocating for patients' wishes and ensuring quality symptom management and support at the end of life.*

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Assess the patient and family to determine if they have written advance directives, such as a durable power of attorney for health care (DPOAHC), a living will, or portable DNR.
- Be aware that nurses have an ethical obligation to provide timely information about expected care outcomes so that patients and families can make the best EOL decisions.
- If needed, teach the patient and family that an advance directive is a written document that specifies what, if any, extraordinary actions that person would want if he or she could no longer make decisions about care.

GET READY FOR THE NCLEX® EXAMINATION! —cont'd

- Be aware that hospice care uses an interdisciplinary approach to assess and address the holistic needs of patients who are dying. Current criteria for Medicare hospice require a prognosis of 6 months or less.

Psychosocial Integrity

- Assess the patient's emotional signs of impending death; assess coping ability of the patient and family or other caregiver.
- Incorporate the patient's personal cultural practices and beliefs regarding death and dying (see [Table 9-2](#)).
- Be aware that older adults who are dying may experience feelings of hopelessness or depression; assess all older adults for indications of these feelings, and collaborate with the health care team to treat them.
- Provide psychosocial interventions to support the patient and family during the dying process, as listed in [Chart 9-3](#).

Physiological Integrity

- Death is defined as the cessation of integrated tissue and organ function, manifested by cessation of heartbeat,

absence of spontaneous respirations, or irreversible brain dysfunction.

- Assess the patient for pain, dyspnea, agitation, nausea, and vomiting, which are common problems at the end of life.
- Recognize that older adults are often underdiagnosed and undertreated for EOL symptoms of distress.
- Assess for the common physical signs of approaching death, as listed in [Chart 9-1](#).
- Medications are frequently given to control dyspnea, pain, nausea and vomiting, and agitation in patients near death (see [Chart 9-4](#)).
- Common complementary and alternative therapies used for symptom management at end of life include aromatherapy, music therapy, and energy therapies, such as Therapeutic Touch.
- Withdrawing or withholding life-sustaining therapy involves withholding treatment that might prolong a patient's life; active euthanasia involves giving a patient a treatment or agent that causes death (see [Table 9-3](#)).

CHAPTER 10

Concepts of Emergency and Trauma Nursing

Answer Key for NCLEX Examination Challenges and
Decision-Making Challenges
Audio Glossary

Key Points
Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Describe the emergency department (ED) environment, including vulnerable populations and interdisciplinary team members.
2. Identify the roles and responsibilities of the health care team members in the ED.
3. Plan and implement best practices to maintain staff and patient safety in the ED.
4. Explain selected core competencies that nurses need to function in the ED.
5. Triage patients in the ED to prioritize the order of care delivery.

6. Prioritize resuscitation interventions based on the primary survey of the injured patient.

Psychosocial Integrity

7. Describe the role of the ED nurse in providing support for families after the death of a loved one.

Physiological Integrity

8. Describe the general process of admission through disposition of a patient in the ED.
9. Prevent or reduce common risk factors in the ED that contribute to adverse events in older adults.

The demand for emergency care in the United States is growing rapidly. Emergency departments (EDs) function as safety nets for communities of all sizes by providing services to both insured and uninsured patients seeking medical care. They are also responsible for public health surveillance and emergency disaster preparedness. Some hospital-based

emergency departments also provide observation, procedural care, and employee health services (Moskop et al., 2009). The role of the ED is so vital that the Centers for Medicare and Medicaid Services (2010) has a process for designating small rural facilities of 25 inpatient beds or fewer as **critical access hospitals** if they provide around-the-clock emergency care

services 7 days per week. Critical access hospitals are considered *necessary providers of health care* to community residents that are not close to other hospitals in a given region.

Because of the multi-specialty nature of the environment, EDs play a unique role within the U.S. health care system. More than 119 million people visit the ED each year (Centers for Disease Control and Prevention [CDC], 2010). The demand for emergency care has greatly increased over the past 15 years, and the health care consumer has higher expectations; however, the capacity to provide necessary resources has not kept pace in most systems. Emergency department crowding occurs when the need for care exceeds available resources in the department, hospital, or both (Howard, 2009).

THE EMERGENCY DEPARTMENT ENVIRONMENT OF CARE

In the emergency care environment, rapid change is the rule. The typical ED is fast paced and, at the height of activity, might even appear chaotic. Patients seek treatment for a number of physical, psychological, spiritual, and social reasons. In general, nurses work in this environment because they dislike routines and thrive in challenging, stimulating work settings. Although most EDs have treatment areas that are designated for certain populations such as patients with trauma or cardiac, psychiatric, or gynecologic problems, care can actually take place almost anywhere. In a crowded ED, patients may receive initial treatment outside of the usual treatment rooms, including the waiting room and hallways.

The ED is typically alive with activity and noise, although the pace decreases at times because arrivals are random. Emergency nurses can expect background sounds that include ringing telephones, monitor alarms, vocal patients, crying children, and radio transmissions between staff and incoming ambulance or helicopter personnel. Interruptions are the norm.

Demographic Data

Staff members in the ED provide care for people across the life span with a broad spectrum of issues, illnesses, and injuries—as well as various cultural and religious values. Especially vulnerable populations who visit the ED include the homeless, the poor, and older adults. During a given shift, for example, the emergency nurse may function as a cardiac nurse, a geriatric nurse, a psychiatric nurse, and a trauma

nurse. Patient acuity runs the range from life-threatening emergencies to minor symptoms that could be addressed in a primary care office or community clinic. Some of the most common reasons that people seek ED care are:

- Abdominal pain
- Chest pain
- Breathing difficulties
- Injuries (especially falls in older adults)
- Headache
- Fever
- Pain (the most common symptom)

Special Nursing Teams

Many EDs have specialized teams that deal with high-risk populations of patients. One example is the forensic nurse examiner team. **Forensic nurse examiners (RN-FNEs)** are educated to obtain patient histories, collect forensic evidence, and offer counseling and follow-up care for victims of rape, child abuse, and domestic violence—also known as *intimate partner violence (IPV)* (Scales et al., 2007). They are trained to recognize evidence of abuse and to intervene on the patient's behalf. Forensic nurses who specialize in helping victims of sexual assault are called *sexual assault nurse examiners (SANEs)* or *sexual assault forensic examiners (SAFEs)*.

Interventions performed by forensic nurses may include providing information about developing a safety plan or how to escape a violent relationship. Forensic nurse examiners document injuries and collect physical and photographic evidence. They may also provide testimony in court as to what was observed during the examination and information about the type of care provided.

The **psychiatric crisis nurse team** is another example of an ED specialty team. Many patients who visit the ED for their acute problems also have chronic mental health disorders. The availability of mental health nurses can improve the quality of care delivered to these patients who require specialized interventions in the ED and can offer valuable expertise to the emergency health care staff. For example, the team evaluates patients with emotional behaviors or mental illness and facilitates the follow-up treatment plan, including possible admission to an appropriate psychiatric facility. These nurses also interact with patients and families when sudden illness, serious injury, or death of a loved one may have caused a crisis. On-site interventions can help patients and families cope with these unexpected changes in their lives.

Interdisciplinary Team Collaboration

The emergency nurse is one member of the large interdisciplinary team who provides care for patients in the ED. A collaborative team approach to emergency care is considered a standard of practice. In this setting, the nurse coordinates care with all levels of health care team providers, from prehospital emergency medical services (EMS) personnel to physicians, hospital technicians, and professional and ancillary staff.

Prehospital Care Providers

Prehospital care providers are typically the first caregivers that patients see before transport to the ED by an ambulance or helicopter (Fig. 10-1). Local protocols define the skill level of the EMS responders dispatched to provide assistance. **Emergency medical technicians (EMTs)** offer basic life

CONSIDERATIONS FOR OLDER ADULTS

Older adults usually visit the ED because of worsening of an existing chronic condition or because the condition affects their ability to perform ADLs. Many older adults seek ED services when they are seriously ill because they do not want to “bother” their health care provider with phone calls (Nolan, 2009).

Older adults are also sometimes admitted from nursing home or assisted-living facilities for procedures (e.g., insertion of a percutaneous endoscopic gastrostomy [PEG] tube or peripherally inserted central catheter [PICC]) or for treatments (e.g., blood transfusions). Some hospitals plan direct admission of the patient to same-day surgery or hold a bed for the procedure or treatment to bypass the ED. This arrangement decreases the patient's wait time and therefore decreases the risks for adverse events, such as pressure ulcer development or hospital-acquired infection.

FIG. 10-1 Advanced life support helicopter arriving at emergency department landing zone. Helicopters are used to rapidly transport critically ill and injured patients to the hospital for emergent care.

FIG. 10-2 Prehospital providers take a patient from the ambulance to be brought into the emergency department.

support (BLS) interventions such as oxygen, basic wound care, splinting, spinal immobilization, and monitoring of vital signs. Some units carry automatic external defibrillators (AEDs) and may be authorized to administer selected drugs such as an EpiPen or nitroglycerin based on established medical protocols. For patients who require care that exceeds BLS resources, paramedics are usually dispatched. **Paramedics** are advanced life support (ALS) providers who can perform advanced techniques, which may include cardiac monitoring, advanced airway management and intubation, establishing IV access, and administering drugs en route to the ED (Fig. 10-2).

The prehospital provider is a key source for valuable patient data. Emergency nurses rely on these providers to be the “eyes and ears” of the health care team in the prehospital setting and to communicate this information to other staff members for continuity of care.

Physicians and Other Health Care Providers

Another integral member of the emergency health care team is the **emergency medicine physician**. These medical professionals receive specialized education and training in emergency patient management. In the past, physicians of all types of skills rotated through the ED. As emergency care became increasingly complex and specialized, emergency medicine became a recognized physician specialty practice, complete with board certification requirements.

The emergency nurse interacts with a number of staff and community physicians involved in patient care but works most closely with emergency medicine physicians. Even though other physician specialists may be involved in ED patient treatment, the emergency medicine physician typically directs the overall care in the department. Many EDs also employ nurse practitioners (NPs) and physician assistants (PAs) to assume designated roles in patient assessment and treatment. Teaching hospitals also have resident physicians who train in the ED. They act in collaboration with or under the supervision of the emergency medicine physician to assist with emergency care delivery.

Support Staff

The emergency nurse interacts on a regular basis with professional and ancillary staff who function in support roles. These personnel include radiology and ultrasound technicians, respiratory therapists, laboratory technicians, social workers, nursing assistants, and clerical staff. Each support staff member is essential to the success of the emergency health care team. The ED nurse is accountable for communicating pertinent staff considerations, patient needs, and restrictions to support staff (e.g., physical limitations, isolation precautions) to ensure that ongoing patient and staff safety issues are addressed. For example, the respiratory therapist can assist the nurse to troubleshoot mechanical ventilator issues. Laboratory technicians can offer advice regarding best practice techniques for specimen collection. During the discharge planning process, social workers or case managers can be tremendous patient advocates in locating community resources, including temporary housing, durable medical equipment (DME), drug and alcohol counseling, health insurance information, and prescription services.

Inpatient Unit Staff

The emergency nurse’s interactions extend beyond the walls of the ED. Communication with staff nurses from the inpatient units is necessary to ensure continuity of patient care. Providing a concise but comprehensive report of the patient’s ED experience is essential for the *hand-off communication* process and patient safety (Mascioli et al., 2009). Information should include the patient’s:

- Situation (reason for being in the ED)
- Brief medical history
- Assessment and diagnostic findings
- Transmission-based precautions needed

- Interventions
- Response to those interventions

The Joint Commission's National Patient Safety Goals (NPSGs) (2010) require hospitals and other health care agencies to use a standardized approach to hand-off communications to prevent errors that are caused by poor or inadequate communication. Many agencies use the SBAR method (situation, background, assessment, response) or some variation of that method to ensure complete and clearly understood communication. Chapter 1 discusses the SBAR technique in more detail.

Both emergency nurses and nurses on inpatient units need to understand the unique aspects of their two practice environments to prevent conflicts. For example, nurses on inpatient units may be critical of the push to move patients out of the ED setting quickly, particularly when the unit activity is high. Similarly, the emergency nurse may be critical of the inpatient unit's lack of understanding or enthusiasm for accepting admissions rapidly. Effective interpersonal communication skills and respectful negotiation can optimize teamwork between the emergency nurse and the inpatient unit nurse. For instance, when ED patient volume or acuity is overwhelming, the unit nurse can volunteer to assist the ED nurse by moving a monitored patient to the hospital bed. The emergency nurse may decide to delay sending admitted patients to inpatient units during change of shift or crisis periods such as a cardiac arrest on the unit, whenever possible.

STAFF AND PATIENT SAFETY CONSIDERATIONS

In the emergency department (ED) setting, staff and patient safety are major concerns (Chart 10-1). *Staff safety* concerns center on the potential for transmission of disease and on personal safety when dealing with aggressive, agitated, or violent patients and visitors.

Staff Safety

The emergency nurse uses Standard Precautions at all times when a potential for contamination by blood or other body fluids exists. Patients with tuberculosis or other airborne pathogens are preferentially placed in a negative pressure room if available. The nurse wears a powered air-purifying respirator (PAPR) or a specially fitted facemask before engaging in any close interaction with these patients. Hostile patient and visitor behaviors also pose injury risks to staff members.

! NURSING SAFETY PRIORITY

Critical Rescue

Be alert for volatile situations or people who demonstrate aggressive or violent tendencies through verbal abuse or acting out. Be sure to follow the hospital's security plan, including looking for an escape route or attempting de-escalation strategies before harm can occur. Emergency visits resulting from gang or domestic violence can produce particularly hazardous conditions.

Many EDs have at least one security guard present at all times for immediate assistance with these situations. Metal detectors may be used as a screening device for patients and visitors who are suspected of having weapons. Strategically located panic buttons and remote door access controls allow

CHART 10-1 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Maintaining Patient and Staff Safety in the Emergency Department

SAFETY CONSIDERATION	INTERVENTIONS TO MINIMIZE RISK
Patient identification	Provide an identification (ID) bracelet for each patient. Use two unique identifiers (e.g., name, date of birth). If patient identity is unknown, use a special identification system.
Injury prevention for patients	Keep rails up on stretcher. Keep stretcher in lowest position. Remind the patient to use call light/bell for assistance. Reorient confused patient frequently. If patient is confused, ask a family member or significant other to remain with him or her. Implement skin prevention measures for patient at risk for skin breakdown.
Risk for errors and adverse events	Obtain a thorough patient and family history. Check the patient for a medical alert bracelet or necklace. Search the patient's belongings for weapons or other harmful devices when he or she has altered mental status.
Injury prevention for staff	Use Standard Precautions at all times. Anticipate hostile, violent patient, family, and/or visitor behavior. Plan options if violence occurs, including assistance from the security department.

staff to get help and secure major ED or hospital entrances. The triage reception area—a particularly vulnerable access point into the ED—is often designed to serve as a security barrier with bullet-proof glass (Laskowski-Jones et al., 2005). Hospitals may even employ canine units made up of specially trained officers and dogs to patrol high-risk areas and respond to handle threatening situations (Johnson & Parker, 2009).

Patient Safety

In addition to concerns about staff safety, some of the most common *patient safety* issues are:

- Patient identification
- Fall risk
- Skin breakdown in vulnerable populations
- High risk for medical errors or adverse events

Hospital emergency departments have unique factors that can affect patient safety. These factors include the provision of complex emergency care, constant interruptions, and the need to interact with the many providers involved in caring for one patient.

Correct *patient identification* is critical in any health care setting. All patients are issued an identification bracelet at their point of entry of the ED—generally at the triage registration desk or at the bedside if emergent needs exist. For patients with an unknown identity and those with emergent conditions that prevent the proper identification process

(e.g., unconscious patient without identification, emergent trauma patient), hospitals commonly use a “Jane/John Doe” or another identification system. Whatever method is used, always verify the patient’s identity using two unique identifiers before each intervention and before medication administration per The Joint Commission’s 2010 National Patient Safety Goals. Examples of appropriate identifiers include the patient’s birth date, agency identification number, home telephone number or address, and/or Social Security number.

Fall prevention starts with identifying people at risk for falls and then applying appropriate fall precautions. Patients can enter the ED without apparent fall risk factors, but because of interventions such as pain medication, sedation, or lower extremity cast application, for example, they can become a risk for falls. Falls can also occur in patients with medical conditions or drugs that cause syncope (“black-outs”). Many older adults also experience orthostatic (postural) hypotension as a side effect of cardiovascular drugs. In this case, patients become dizzy when changing from a lying or sitting position.

NURSING SAFETY PRIORITY

Action Alert

Help patients move slowly from a supine to an upright position and when ambulating, if needed. Also, confirm that siderails are up and locked on stretchers, that the call bell or light is within reach, and that a patient’s fall risk is communicated clearly to visitors and staff members who may assume responsibility for care.

Older adults who are on beds or stretchers should *always* have all siderails up and the bed or stretcher in the lowest position. Access to a call bell or light is especially important; instruct the patient to call for the nurse if assistance is needed rather than attempt independent ambulation. Many older adults have difficulty adjusting to the noise and pace of the ED and/or have illnesses or injuries that cause delirium, an acute confusional state. Reorient the patient frequently, and re-assess mental status. Undiagnosed delirium increases the risk for mortality for older adults who are admitted to the hospital. Assess the need for a family member, significant other, or sitter to stay with the patient to prevent falls and assist with reorientation. Additional safety strategies are listed in [Chart 10-1](#).

Some patients spend a lengthy time on stretchers while awaiting unit bed availability—possibly as long as 1 to 2 days in hospitals. During that time, basic health needs require attention, including providing nutrition, hygiene, and privacy for all ED patients. Waiting in the ED can cause increased pain in patients with back pain or arthritis.

Protecting skin integrity also begins in the ED. Emergency nurses need to assess the skin frequently and implement preventive interventions into the ED plan of care, especially when caring for older adults or those of any age who are immobilized. Interventions that promote clean, dry skin for incontinent patients, mobility techniques that decrease shearing forces when moving the immobile patient, and routine turning help prevent skin breakdown. [Chapter 27](#) describes additional nursing interventions for preventing skin breakdown.

A significant risk for all patients who enter the emergency care environment is the *potential for medical errors or adverse events*, especially those associated with medication administration. The episodic and often chaotic nature of emergency management in an environment with frequent interruptions can easily lead to errors.

To reduce error potential, the emergency nurse makes every attempt to obtain essential and accurate medical history information from the patient, family, or reliable significant others as necessary. When dealing with patients who arrive with an altered mental status, a quick survey to determine whether the person is wearing a medical alert bracelet or necklace is important to gain medical information. In addition, a two-person search of patient belongings may yield medication containers; the name of a physician, pharmacy, or family contact person; or a medication list. In this case, the nurse serves as a detective to find clues, which may not only promote safety but also help determine the diagnosis and influence the overall emergency treatment plan. Automated electronic tracking systems are also available in some EDs to assist staff in identifying the location of patients at any given time and in monitoring the progress of care delivery during the visit. These valuable safety measures are especially important in large or busy EDs with a high population of older adults (Laskowski-Jones, 2008).

In addition to falls and pressure ulcer development, another adverse event that can result from a prolonged stay in the ED is a *hospital-acquired infection*. Older adults, in particular, are at risk for urinary tract or respiratory infections. Patients who are immune suppressed, especially those on chronic steroid therapy or immune modulators, are also at a high risk. Nurses and other ED personnel need to wash their hands frequently and thoroughly or use hand sanitizers to help prevent pathogen transmission.

DECISION-MAKING CHALLENGE

Quality Improvement

The case manager and quality improvement coordinator of a large metropolitan ED conducted a retrospective chart review to determine which patient population is most likely to develop pressure ulcers after admission to the hospital from the ED. In your staff meeting, they report that adults older than 80 years admitted from long-term care facilities (nursing homes) and staying 10 hours or more in the ED are most likely to develop pressure ulcers after hospital admission.

1. Why are pressure ulcers common in older adults, especially those living in a nursing home?
2. What plan of action do you think would help decrease the incidence of pressure ulcer development in the identified highest-risk population?
3. What role might you play in implementing this plan as an ED nurse?
4. With what members of the interdisciplinary team might this plan be implemented?
5. What would be a reasonable outcome as a result of your plan of action?

SCOPE OF EMERGENCY NURSING PRACTICE

The scope of emergency nursing practice encompasses management of patients across the life span—from birth through death—and all health conditions that prompt a person of any age to seek emergency care.

Core Competencies

Emergency nursing practice requires that nurses be skilled in patient assessment, priority setting and clinical decision making, multitasking, and communication. A sound knowledge base is also essential. Flexibility and adaptability are vital

traits because situations within the ED, as well as individual patients, can change rapidly.

Like that of any nurse in practice, the foundation of the emergency nurse's skill base is *assessment*. He or she must be able to rapidly and accurately interpret assessment findings according to acuity and age. For example, mottling of the extremities may be a normal finding in a newborn but it may indicate poor peripheral perfusion and a shock state in an adult.

CONSIDERATIONS FOR OLDER ADULTS

Some older adults may not be able to provide an accurate history because of memory loss or acute delirium. If possible, review their prior hospitalization records to obtain complete histories or ask a family member or friend for pertinent information. Older adults usually have many pre-existing diseases (comorbidities) that must be considered as part of the assessment. *Knowing the history is vital because these conditions might adversely affect or complicate the cause for the ED visit.* For example, a patient who has rib fractures but has a history of chronic obstructive pulmonary disease (COPD) may not be able to maintain adequate oxygenation without endotracheal intubation and mechanical ventilatory support in the ED.

Another consideration for older adult assessment is that their presenting symptoms are often different or less specific than those of younger adults. For example, increasing weakness, fatigue, and confusion may be the only admission concerns. These vague symptoms can be caused by serious illnesses, such as an acute MI, urinary tract infection, or pneumonia. Diagnosing older adults often keeps them in the ED for extended periods, which can lead to patient safety concerns as discussed on p. 122.

Another skill for the emergency nurse is *priority setting*, which is essential in the triage process and is described on p. 127. Priority setting depends on accurate assessment, as well as good critical thinking and clinical decision-making skills. These skills are generally gained through hands-on clinical experience in the ED. However, discussion of case studies and the use of human patient simulation and simulation software can help prepare nurses to acquire this skill base in a nonthreatening environment and then apply it in the actual clinical situation (Wolf, 2008).

The knowledge base for emergency nurses is broad and ranges from critical care emergencies to less common problems, such as snakebites and hazardous materials contamination (see [Chapters 11 and 12](#)). ED nurses also learn to recognize and manage the legal implications of societal problems such as domestic violence, elder abuse, and sexual assault.

Although most EDs have physicians available around the clock who are physically located within the ED, the nurse often initiates interdisciplinary protocols for lifesaving interventions such as cardiac monitoring, oxygen therapy, insertion of IV catheters, and infusion of appropriate parenteral solutions. In many EDs, nurses function under clearly defined medical protocols that allow them to initiate drug therapy for emergent conditions such as anaphylactic shock and cardiac arrest. Emergency care principles extend to knowing what essential laboratory and diagnostic tests may be needed and, when necessary, obtaining them.

The emergency nurse must also be proficient in performing a variety of technical skills (multitasking), sometimes in a stressful, high-pressure environment such as a cardiac or trauma resuscitation. In addition to basic skills,

he or she may also need to be proficient with critical care equipment, such as invasive pressure monitoring devices and mechanical ventilators. This type of equipment is commonly found in EDs that are part of Levels I and II trauma centers.

The nurse also assists the physician with a number of procedures. Knowledge and skills related to procedural setup, patient preparation, teaching, and postprocedure care are key aspects of emergency nursing practice. Common ED procedures include:

- Simple and complex suturing for wound closure
- Foreign body removal
- Central line insertion
- Endotracheal intubation and initiation of mechanical ventilation
- Transvenous pacemaker insertion
- Lumbar puncture
- Pelvic examination
- Chest tube insertion
- Peritoneal lavage
- Paracentesis
- Fracture management

More than one nurse may be necessary to assist with some procedures. For example, if moderate sedation is used to produce amnesia and relaxation during fracture reduction, one nurse assists the physician with the actual procedure while the other nurse monitors the patient before, during, and after the moderate sedation medications are administered.

Finally, an essential aspect of the emergency nurse's skill base is *communication*. The ED environment is complex; therefore multiple barriers to effective communication are likely. One common barrier is the patient's cultural beliefs and practices, especially if they differ from those of the health care team. Assess each patient as an individual, and be careful not to stereotype anyone based on his or her ethnicity or religion.

CULTURAL AWARENESS

Be aware of the various cultural and religious values of patients that may influence care. Many people have distinct beliefs that must be respected in the health care setting. For example, some Mexican Americans are modest and do not like to have their bodies exposed. They often tend to be very family-oriented and affectionate toward each other.

Patients with language barriers can present a challenge. The Spanish-speaking population in the United States, for instance, is rapidly increasing. When a bilingual staff member is not available to interpret, access resources such as telephone language lines and dedicated interpreters contracted by the hospital.

A religious belief system can also affect the delivery of care. For example, Jehovah's Witness patients do not accept blood transfusions. [Chapter 4](#) describes common belief systems and their impact of patient care.

ED crowding and insufficient nursing personnel to meet the demand for services also create difficulties with communication of pertinent patient information and quality of written documentation. The high-stress ED environment can negatively affect effective interpersonal behaviors, particularly when nurses must deal with angry, violent, or demanding patients.

TABLE 10-1 DESCRIPTIONS OF TRAINING AND CERTIFICATIONS FOR EMERGENCY NURSING

CERTIFICATION	DESCRIPTION
Basic Life Support (BLS) (required)	Noninvasive assessment and management skills for airway maintenance and cardiopulmonary resuscitation (CPR)
Advanced Cardiac Life Support (ACLS) (usually required)	Invasive airway management skills, pharmacology, and electrical therapies, special resuscitation
Pediatric Advanced Life Support (PALS) (may be required)	Neonatal and pediatric resuscitation
Certified Emergency Nurse (CEN) (optional)	Validates core emergency nursing knowledge base

**NCLEX EXAMINATION CHALLENGE****Safe and Effective Care Environment**

An 88-year-old man is admitted to the ED from home with weakness and acute confusion. What is the nurse's priority for his care to maintain client safety?

- A. Assess his mental status every 30 minutes.
- B. Ensure that siderails are raised on his stretcher.
- C. Check his bowel sounds for intestinal obstruction.
- D. Teach him to move slowly when walking.

Training and Certification

Two general types of certification are referred to in emergency nursing practice: the “certification” that marks successful completion of a particular course of study; and emergency nursing specialty certification (Table 10-1). As part of the orientation and employment requirements for staff nurses in most U.S. EDs, successful completion of the Basic Life Support (BLS) for Healthcare Providers and Advanced Cardiac Life Support (ACLS) provider courses through the American Heart Association is necessary. These courses provide instruction in fundamental, evidence-based management theory and techniques for cardiopulmonary resuscitation (CPR). Course participants include physicians, nurses, and prehospital personnel. BLS emphasizes hands-on noninvasive assessment and management skills to restore an effective airway, breathing, and circulation. The participant performs basic airway maneuvers and CPR. The ACLS course builds on the BLS content to include advanced concepts in cardiac monitoring, invasive airway management skills, pharmacologic and electrical therapies, intravascular access techniques, special resuscitation situations, and post-resuscitation management considerations.

EMERGENCY NURSING PRINCIPLES**Triage**

ED **triage** is an organized system for sorting or classifying patients into priority levels depending on illness or injury severity. The organization of emergency care and the ED is

structured through triage principles. The key concept is that patients who present to the ED with the highest acuity needs receive the quickest evaluation, treatment, and prioritized resource utilization such as x-ray studies, laboratory work, and computed tomography (CT) scans. These patients also have priority for hospital service areas, such as the operating room or cardiac catheterization laboratory. A person with a lower acuity problem may wait longer in the ED because the higher acuity patient is moved to the “head of the line.” The staff may need to explain this system to the patient and family who may not understand why other patients are treated first.

The triage nurse is the gatekeeper in the emergency care system. When patients present to the ED, regulatory standards dictate that a registered nurse (RN), physician, or physician assistant (PA) perform a rapid assessment to determine triage priority. However, the RN is typically the person assigned to perform the triage function in most hospitals. The triage nurse requires appropriate training and experience in both emergency nursing and triage decision-making concepts. In some instances, the triage nurse may seek the input of an emergency physician, advanced practice nurse (e.g., nurse practitioner [NP]), or PA to help establish the acuity level if the patient's presentation is highly unusual.

Based on the triage priority, patients may be rushed into a treatment room, directed to a lower acuity area within the ED, or asked to sit in the waiting room. Variations on this theme include:

- Triage nurse–initiated protocols for laboratory work or diagnostic studies that may be performed before the patient is actually evaluated by a physician
- Initiation of care while the patient is on a stretcher in the hallway of a crowded ED

These protocols are especially beneficial for certain populations who require rapid diagnosis and treatment within a defined time frame from ED arrival to meet established standards of care. Examples are patients with chest pain or those with a clinical presentation that seems to indicate stroke or pneumonia (VanHoy & Laskowski-Jones, 2006).

Emergent, Urgent, and Nonurgent Categories

Many triage systems can be used by a hospital ED. Any system must be applied consistently by triage nursing staff and endorsed by the emergency medicine physician staff. Based on the severity of the patient's condition, a well-known triage scheme used in the United States is the three-tiered model of “emergent, urgent, and nonurgent” (Table 10-2). In this system, for example, a patient experiencing crushing substernal chest pain, shortness of breath, and diaphoresis would be classified as emergent and triaged immediately to a treatment room within the ED. Similarly, a critically injured trauma patient or a person with an active hemorrhage would also be prioritized as emergent (Fig. 10-3). The **emergent triage** category implies that a condition exists that poses an immediate threat to life or limb.

The **urgent triage** category indicates that the patient should be treated quickly but that an immediate threat to life does not exist at the moment. Reassessment is needed if a physician cannot evaluate the patient in a timely manner. In people with evidence of clinical deterioration, triage priority may be upgraded from urgent to emergent. Examples of patients who typically fall into the urgent category are those with a new onset of pneumonia (as long as respiratory failure

TABLE 10-2 THREE-TIERED TRIAGE SYSTEM AND EXAMPLES OF PATIENTS TRIAGED IN EACH TIER

TIER LEVEL	EXAMPLES OF PATIENTS TRIAGED IN EACH TIER
Emergent (life threatening)	Respiratory distress Chest pain with diaphoresis Active hemorrhage Unstable vital signs
Urgent (needs quick treatment, but not immediately life threatening)	Severe abdominal pain Renal colic Displaced or multiple fractures Complex or multiple soft tissue injuries New-onset respiratory infection, especially pneumonia in older adults
Nonurgent (could wait several hours if needed without fear of deterioration)	Skin rash Strains and sprains "Colds" Simple fracture

FIG. 10-3 Emergency team assessing emergent triaged patient.

does not appear imminent), renal colic, complex lacerations not associated with major hemorrhage, displaced fractures or dislocations, and temperature greater than 101° F (38.3° C). Those categorized as **nonurgent** can generally tolerate waiting several hours for health care services without a significant risk for clinical deterioration. Conditions within this classification include patients with sprains and strains, simple fractures, "cold" symptoms, and skin rashes.

Other Multi-Tiered Models

To further sort patient conditions within an acuity classification or triage priority system, four- and five-tier triage models also exist. Such models are based either on comprehensive lists of conditions that indicate the particular triage priority to which a patient should be assigned or on the nature of resources that a patient will use in the ED setting. A patient situation may generate various triage classifications in different hospitals depending on the triage priority system used at that particular institution. Some schemes may even take into account the presence of pre-existing conditions such as a

history of anticoagulant use, diabetes, heart disease, and organ transplantation.

It is surprising that there is no universally accepted triage system recognized in the United States. Thus there is no standardization of triage acuity data to compare patient acuity among hospitals. Medical providers, health insurance companies, and patients often disagree on the definition of an emergent versus a nonurgent ED visit, making it essential to use a practical triage system to maintain department efficiency (Huryk, 2006). The Emergency Nurses Association in collaboration with the American College of Emergency Physicians studied the available research literature on acuity scales and concluded that two standardized five-level systems, the **Emergency Severity Index (ESI)** and the **Canadian Triage Acuity Scale (CTAS)**, are the most reliable (Fernandes et al., 2005). The ESI model uses an algorithm that fosters rapid, reliable, and clinically pertinent categorization of patients into five groups, from level 1 (emergent) to level 5 (nonurgent). The CTAS model differs from ESI in that lists of descriptors are used to establish the triage level.

Whatever triage model is used, triage nurses must employ a systematic approach, apply solid clinical decision-making skills, and maintain a caring ethic. Compassion fatigue, or burn-out, can hinder objectivity in dealing with patients who present to the ED. A biased approach threatens the ED nurse's ability to triage patients accurately. Mistriage is a patient safety risk that can be the "root cause" of delayed or inadequate treatment with potentially deadly consequences.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

The nurse assesses five clients who were just admitted to the ED. Triage these clients in the order that they should receive care.

- ☐ A. 27-year-old with flu-like symptoms
- ☐ B. 47-year-old with an abdominal gunshot wound
- ☐ C. 55-year-old with crushing chest pain
- ☐ D. 72-year-old with a possible hip fracture
- ☐ E. 90-year-old with a probable urinary tract infection

Disposition

At the conclusion of the assessment, the physician must make a decision regarding patient disposition (i.e., where the patient should go after being discharged from the ED). Should the patient be admitted to the hospital, transferred to a specialty care center, or be discharged to home with instructions for continued care and follow-up? Usually, the answer is straightforward. A patient who has an evolving myocardial infarction, stroke, or acute surgical need is admitted.

Sometimes, though, the ED disposition decision is less clear. Often the emergency nurse and physician discuss this decision collaboratively. The nurse may have a greater sense of how well a patient will manage in a home setting depending on whether other family members or friends are available to assist and are reliable. For example, in the event a patient with a minor head injury has suffered a loss of consciousness, someone is typically expected to remain with that person for the first 12 to 24 hours to be sure that he or she does not show any evidence of neurologic deterioration. Another common scenario involves the potential risk to the patient in cases of actual or suspected domestic violence. If discharge to home is not deemed safe, the patient may be admitted to the hospital

in an observation status until resources can be organized to provide for a safe environment. Coordinate the discharge plan and continuing care with the social worker or case manager.

CONSIDERATIONS FOR OLDER ADULTS

If discharge from the ED to home is possible, ensure that safety issues are considered. For example, evaluate the patient's prescription and over-the-counter medications to determine if the drug regimen should be continued. If not, be sure that the patient and family member or significant other has the new information in writing and that it is explained verbally. If needed, assess whether the patient has someone who can pre-pour weekly medications to ensure accuracy and prevent adverse drug events.

To prevent future ED visits, screen older adults per agency policy for functional assessment, cognitive assessment, and risk for falls. Depression screening is also important because suicide rates are two times higher among older adults when compared with younger adults. White men older than 85 years are at the highest risk (Nolan, 2009).

More than half of all older patients are admitted to the hospital directly from the ED (Nolan, 2009). If hospitalization is needed, determine if the patient has advance directives or is able to make decisions about advance directives before admission. If the patient was admitted from a nursing home, contact the facility to let them know the patient's status. If the patient was receiving home health services, notify the agency about the hospital admission. Contact the patient's primary physician and designated family member if he or she is not present with the patient.

Case Management

Some EDs employ registered nurse case managers who screen ED patients and intervene when necessary to arrange appropriate referral and follow-up. This is an evolving role in the ED setting that can be beneficial in providing comprehensive care and as a strategy to avoid inappropriate use of resources.

ED case managers, supported by electronic information systems, can review the ED census on both a "real-time" and a retrospective basis to determine which patients have visited the ED frequently in a given period. The case manager can then determine the reasons they sought emergency services, such as lack of a primary health care provider, exacerbation ("flare-up") of a chronic condition, or lack of health education. Case management interventions include facilitating referrals to primary care providers who are accepting new patients or to subsidized community-based health clinics for patients or families in need of routine services.

For those with needs related to chronic conditions, the case manager can arrange referral into appropriate disease management programs in the community if available. Disease management programs are specific to a particular condition such as asthma, COPD, diabetes, hypertension, heart failure, and renal failure. They help patients learn how to manage their condition on a day-to-day basis to prevent exacerbations or clinical deterioration. The desired outcome is to keep the person out of the hospital as long as possible. Health teaching is a key component of these programs. For other health teaching needs, the ED case manager directs the patient to the appropriate educational resources such as a health educator, registered dietitian, or community organization (e.g., the American Cancer Society, the American Heart Association).

Other functions of the ED case manager might include working with staff to plan disposition for homeless people,

locating a safe environment for victims of domestic violence or elder abuse, or providing information on resources for low-cost or free prescriptions. Homeless adults often have multiple chronic medical illnesses for which they visit emergency departments frequently. A large study of homeless adults with chronic medical illnesses demonstrated a decrease in ED visits and hospital admissions as a result of an organized follow-up system for housing and ongoing case management support (see the Evidence-Based Practice box on p. 130).

Patient and Family Education

A key role of the emergency nurse is health teaching. At the most basic level, nurses review discharge instructions with the patient and family before signing them out of the department.

CULTURAL AWARENESS

Most discharge instructions are either preprinted or computer generated and can be customized to address the patient's needs. Consider his or her reading level, primary language, and visual acuity. Educational materials and instructions should be available at no higher than the 6th-grade reading level. For patients who have English as a second language, many hospitals have educational materials available in Spanish and other regional languages. However, interpreters may be necessary to assist the health care provider customize the information appropriately. For older adults and others with vision deficits, large-print materials may be helpful.

In addition to discharge instructions, the ED environment and community-at-large present many opportunities for health education. Emergency nurses are in an ideal position to educate the public about wellness and injury-prevention strategies. If the patient presented after a motor vehicle crash, for instance, the nurse can reinforce the need to wear seat belts or use child safety seats correctly. ED visits that result from mishaps in the home provide an excellent opportunity to discuss home safety issues (e.g., the need for smoke detectors and carbon monoxide detectors) and fall prevention tips (e.g., the need for proper lighting, removal of throw rugs). Injury is not the only topic that affords a teaching opportunity. A new onset or an exacerbation of a medical condition also allows for education, such as how to measure blood glucose and ways to control blood pressure or reduce the risk for heart disease.

Death in the Emergency Department

Not all critically ill or injured patients who come to the ED can be saved. Sometimes a patient's death is expected by family members, typically when they have dealt with a loved one's terminal condition or age-related decline. Usually, however, a death in the ED is a sudden and unexpected event that produces a state of crisis and chaos for family and significant others. Emergency department staff members need to address the needs of the family members in this overwhelming time.

If resuscitation efforts are still underway when the family arrives, one or two family members may be given the opportunity to be present during lifesaving procedures. Family presence during resuscitation is gaining wider acceptance in the health care community.

If the patient has died by the time family members arrive, ED staff members must try to prepare the body and the room

EVIDENCE-BASED PRACTICE

Reducing ED Visits By Homeless Adults

Sadowski, L.S., Kee, R.A., VanderWeele, T.J., & Buchanan, D. (2009). Effect of a housing and case management program on emergency department visits and hospitalizations among chronically ill homeless adults. *JAMA: The Journal of the American Medical Association*, 301(17), 1771-1778.

Homeless adults, especially those with chronic medical illnesses, are frequent users of ED and hospital services. The researchers conducted a randomized controlled trial study at a public teaching hospital and a private nonprofit hospital in Chicago. Participants in the study were 407 social worker-referred homeless adults with chronic illnesses who used ED services and were hospitalized over a 3-year period.

The study group received transitional housing after hospital discharge followed by placement in long-term housing. Case management services were also offered at hospital, transitional housing, and stable housing sites. The non-study group received usual discharge planning through hospital social services. The results clearly demonstrated that housing and case management interventions reduced ED visits by 24% and subsequent hospitalizations by 29% over 18 months. There were no significant differences between hospital outcomes.

Level of Evidence: 1

The strengths of this study are the rigorous design using randomization and a large sample that followed patients over a long period of time.

Commentary: Implications for Practice and Research

ED nurses are involved in quality improvement activities, including ways to decrease ED visits or recurrent visits by patients who are chronically ill. The homeless are frequent users of ED services who rely solely on the hospital for medical and nursing care. Follow-up resources and systems to assist vulnerable populations, such as the homeless, need to be developed to improve quality care and decrease medical costs from multiple hospital stays.

for viewing by the family. However, certain types of ED deaths may require forensic investigation or become medical examiner's cases. Therefore ED staff may not be able to remove IV lines and indwelling tubes or clean the patient's skin if these actions could potentially damage evidence. Trauma deaths, suspected homicide, or abuse cases always fall into this category. In these situations, covering the body with a sheet or blanket while leaving the patient's face exposed and dimming the lights may be all that can be done in the ED before family viewing.

When dealing with family members in crisis, communication that is simple and concrete is best. Words such as *death* or *died*, although seemingly harsh, create less confusion than terms such as *expired* or *passed away*. Demonstrate caring, compassion, and empathy during all interactions, even in periods of heightened emotions. Intense grief can provoke a range of family reactions from silence to violence. If available, coordinate with crisis staff (social workers or psychiatric nurses) to assist families during this time. Offer the family the option of speaking with clergy or calling someone of their choice for additional support. A family member may need to be admitted to the ED to be treated for anxiety or physical manifestations of stress such as chest pain, difficulty breathing, or severe headache.

Dealing with death is often difficult for ED personnel, especially during busy periods when the ability to console family members may be limited. In response, some emergency departments have developed bereavement committees that focus on meeting the needs of grieving families. Activities such as sending sympathy cards, attending funerals, making follow-up phone calls, and creating memory boxes are common. These actions help communicate caring and compassion after the moment of crisis.

TRAUMA NURSING PRINCIPLES

The general public tends to use the term *trauma* to mean any type of crisis ranging from a heart attack to psychological stress. Among health care professionals, though, **trauma** refers to bodily injury. More than 180,000 people in the United States die each year as a result of injuries, and nearly 2 million are hospitalized, often with permanent and disabling consequences (National Center for Injury Prevention and Control, 2010). Injuries can be categorized as either intentional (i.e., assault, homicide, suicide) or unintentional (i.e., accidents). *Unintentional injury*, such as a motor vehicle crash, is the leading cause of death for Americans younger than 35 years and is one of today's most significant public health problems (National Center for Injury Prevention and Control, 2010).

Injury management is a key component of emergency department services. About 30 million people in the United States visit the ED each year to receive treatment for injuries (National Center for Injury Prevention and Control, 2010). Therefore an important part of emergency nursing practice is a core competency in general trauma care. For emergency nurses who work in accredited trauma centers, opportunities typically exist to further develop expertise in trauma nursing through ongoing clinical practice, specialty training programs, and continuing education. Trauma nursing is a field that encompasses the continuum of care from injury prevention and prehospital services, to acute care, rehabilitation, and, ultimately, community reintegration.

Trauma Centers and Trauma Systems

Trauma centers have their roots in military medicine. Injured soldiers who received rapid transport from the battlefield and treatment from skilled health care personnel had a survival advantage in the mobile army surgical hospital (MASH) units first deployed in the Korean and Vietnam wars. Consequently, the MASH unit became the original model for the development of civilian trauma centers. Today's **trauma center** in the United States is a specialty care facility that provides competent and timely trauma services to patients, depending on its designated level of capability.

Trauma Centers

Not all EDs that offer around-the-clock emergency services are trauma centers. The American College of Surgeons Committee on Trauma (2006) has set forth national standards for trauma center accreditation and categorizes the resource requirements necessary for the highest capability trauma center (Level I) to the lowest (Level IV) (Table 10-3).

A **Level I trauma center** is a regional resource facility that is capable of providing leadership and total care for every aspect of injury, from prevention through

TABLE 10-3 LEVELS AND FUNCTIONS OF TRAUMA CENTERS

LEVELS OF TRAUMA CENTER	FUNCTIONS OF TRAUMA CENTER
Level I	Usually located in large teaching hospital systems in densely populated areas. Provides full continuum of trauma care for all patients.
Levels II and III	Both located in community hospitals. Level II provides care to most injured patients; Level III stabilizes patients with major injuries. Both levels often transport patients to higher trauma center levels if patient needs exceed resource capabilities.
Level IV	Located in rural and remote areas. Provides advanced life support. Transports to higher trauma center levels when able.

rehabilitation. These centers also have a responsibility to offer professional and community education programs, conduct research, and participate in system planning. Because a significant resource and experience commitment is required to maintain strict accreditation standards, Level I trauma centers are usually located in large teaching hospitals and serve dense population areas.

Level II trauma centers are usually located in community hospitals and are capable of providing care to the vast majority of injured patients. However, a Level II trauma center may not be able to meet the resource needs of patients who require very complex injury management, such as those in need of advanced surgical care. These people are generally transferred to a Level I trauma center for specialty care. In communities without a Level I trauma center, Level II centers play a significant leadership role in injury management, education, prevention, and emergency preparedness planning.

A **Level III trauma center** is a critical link to higher capability trauma centers in communities that do not have ready access to Level I or Level II centers. The primary focus is injury stabilization and patient transfer. Level III trauma centers are usually found in smaller, rural hospitals and serve areas with low population density. Because Level III trauma centers have general surgeons and orthopedic surgeons immediately available, patients with some major injuries may be admitted for care. However, if the injuries are severe or critical, transfer to a Level I or II trauma center occurs after ED assessment, resuscitation, and stabilization—sometimes after emergent, lifesaving surgery. Patients are typically transported out in either an advanced life support ambulance or helicopter with critical care transport personnel in attendance.

The function of a **Level IV trauma center** is to offer advanced life support care in rural or remote settings that do not have ready access to a higher-level trauma center, such as a ski area. Patients are stabilized to the best degree possible before transfer, using available personnel such as advanced practice nurses, physician assistants, nurses, and paramedics. Resources, including the consistent availability of a physician, may be extremely limited. Transport time to the final care

center can be prolonged because of both distance and bad weather conditions that may prevent transfer by air.

Level III and Level IV trauma centers establish close working relationships with Level I and Level II trauma centers. Based on accreditation standards, care providers at Levels I and II trauma centers have a responsibility to readily accept injured patients in transfer. They provide timely feedback to trauma personnel at referring hospitals and share expertise by offering educational opportunities to advance trauma care delivery in the region. In addition, personnel from all levels of trauma centers participate in focused system improvement and patient safety initiatives that enhance quality of care and solve identified problems.

Trauma Systems

Trauma centers save lives—but a trauma center is only as good as the overall trauma system that supports it. A **trauma system** is an organized and integrated approach to trauma care designed to ensure that all critical elements of trauma care delivery are aligned to meet the injured patient's needs. These elements include (Cooper & Laskowski-Jones, 2006):

- Access to care through communication technology (e.g., an enhanced 911 service)
- Timely availability of prehospital emergency medical care
- Rapid transport to a qualified trauma center
- Early provision of rehabilitation services
- System-wide injury prevention, research, and education initiatives

The overall desired outcome of an organized trauma system is to enable an injured patient not only to recover from trauma but also to return to a productive role in society.

A well-functioning trauma system is also essential to general public health and safety. It provides the structure necessary for disaster readiness and community emergency preparedness (see [Chapter 12](#)). Although most states now have at least some basic elements of a trauma system in place, significant gaps still exist in many regions.

Mechanism of Injury

The **mechanism of injury (MOI)** describes how the patient's traumatic event occurred, such as a high-speed motor vehicle crash, a fall from a standing height, or a gunshot wound to the torso. Knowing key details about the MOI can provide insight into the energy forces involved and may help trauma care providers predict injury types and, in some cases, patient outcomes. Prehospital care providers report the MOI as a communication standard when handing off care to ED and trauma personnel. Similarly, patients who present to the ED for medical care will often relate the MOI by describing the particular chain of events that caused their injuries.

Two of the most common injury-producing mechanisms are blunt trauma and penetrating trauma. **Blunt trauma** results from impact forces like those sustained in a motor vehicle crash, a fall, and an assault with fists, kicks, or a baseball bat. **Blast effect** from an exploding bomb also causes blunt trauma. The energy transmitted from a blunt trauma mechanism, particularly the rapid **acceleration-deceleration** forces involved in high-speed crashes or falls from a great height, produces injury by tearing, shearing, and compressing

anatomic structures. Trauma to bones, blood vessels, and soft tissues occurs.

Penetrating trauma is caused by injury from sharp objects and projectiles. Examples are wounds from knives, ice picks, and other comparable implements, as well as bullets or pellets. Fragments of metal, glass, or other materials that become airborne in an explosion (shrapnel) can also produce penetrating trauma. Each mechanism has the risk for specific injury patterns and severity that the trauma team considers when planning diagnostic evaluation and management strategies. Certain injury mechanisms, such as a gunshot wound to the chest or abdomen or a stab wound to the neck, are so highly associated with life-threatening consequences that they automatically require trauma team intervention for a rapid and coordinated resuscitation response.

Primary Survey and Resuscitation Interventions

A basic tenet of emergency care in any environment is scene safety. In the prehospital setting, emergency care providers must ensure that they are aware of any hazards that might pose a threat to rescuers and take actions to decrease or eliminate the risk. This same concept applies to the hospital ED setting. Before engaging in trauma resuscitation as a nurse member of the trauma team, keep in mind that there is a high risk of contamination with blood and body fluids. For this reason, use Standard Precautions in *all* resuscitation situations and at other times when exposure to blood and body fluids is likely. Proper attire consists of an impervious cover gown, gloves, eye protection, a facemask, and surgical cap, as well as shoe covers (if *significant* blood loss is anticipated, such as during an ED procedure).

The initial assessment of the trauma patient is called the **primary survey**, which is an organized system to rapidly identify and effectively manage immediate threats to life. The primary survey is based on a standard “ABC” mnemonic plus a “D” and “E” for trauma patients: airway/cervical spine (A); breathing (B); circulation (C); disability (D); and exposure (E). Resuscitation efforts occur simultaneously with each element of the primary survey (American College of Surgeons Committee on Trauma, 2008; Laskowski-Jones, 2009). Even though the resuscitation team may encounter multiple clinical problems or injuries, issues identified in the primary survey are managed before the team engages in interventions of lower priority, such as splinting fractures and dressing wounds.

A: Airway/Cervical Spine

Like for any patient, the highest priority intervention is to establish a patent airway. Even minutes without an adequate oxygen supply can lead to brain injury that can progress to anoxic brain death.

! NURSING SAFETY PRIORITY

Critical Rescue

Clear the airway of any secretions or debris either with a suction catheter or manually if necessary. Protect the cervical spine in any trauma patient with the potential for spinal injury by manually aligning the neck in a neutral, in-line position and using a jaw-thrust maneuver when establishing an airway. Provide supplemental oxygen for all patients who require resuscitation.

FIG. 10-4 Emergency department trauma resuscitation room. Wearing Standard Precautions attire, trauma team members prepare to intubate the injured patient.

In general, a non-rebreather mask is best for the spontaneously breathing patient. Bag-valve-mask (BVM) ventilation with the appropriate airway adjunct and a 100% oxygen source is indicated for the person who needs ventilatory assistance during resuscitation. A patient with significantly impaired consciousness requires an endotracheal tube and mechanical ventilation (American College of Surgeons Committee on Trauma, 2008) (Fig. 10-4).

B: Breathing

After the airway is successfully secured, breathing becomes the next priority in the primary survey. *This assessment determines whether or not ventilatory efforts are effective—not only whether or not the patient is breathing.* Listen to breath sounds and evaluate chest expansion, respiratory effort, and any evidence of chest wall trauma or physical abnormalities. Both apneic patients and those with poor ventilatory effort need BVM ventilation for support until endotracheal intubation is performed and a mechanical ventilator is used. If cardiopulmonary resuscitation (CPR) becomes necessary, the mechanical ventilator is disconnected and the patient is manually ventilated with a BVM device. Lung compliance can be assessed through sensing the degree of difficulty in ventilating the patient with the BVM.

Another lifesaving intervention that may be performed in this phase is chest decompression using a needle or chest tube

thoracostomy to vent trapped air. The main indication for chest decompression is clinical evidence of a tension pneumothorax, which can pose a critical threat to both breathing and circulation. Symptoms include:

- Decreased to absent breath sounds over the affected side
- Respiratory distress
- Hypotension
- Jugular vein distention
- Tracheal deviation (late symptom)

If unrelieved, a tension pneumothorax causes mediastinal shift, cardiovascular collapse, and death. Causes of tension pneumothorax include barotrauma from BVM ventilation or other positive-pressure ventilation, blunt or penetrating chest trauma, and progression of a simple pneumothorax. Further information on types and management of pneumothorax are discussed in [Chapter 34](#).

C: Circulation

When effective ventilation is ensured, the priority shifts to circulation. The adequacy of heart rate, blood pressure, and overall perfusion becomes the focus of the assessment. Common threats to circulation include cardiac arrest, myocardial dysfunction, and hemorrhage leading to a shock state. Interventions are targeted at restoring effective circulation through cardiopulmonary resuscitation, hemorrhage control, IV vascular access with fluid and blood administration as necessary, and drug therapy. *External hemorrhage is usually quite obvious and best controlled with firm, direct pressure on the bleeding site with thick, dry dressing material. This method is effective in decreasing blood flow for the majority of wounds—even those caused by amputations (Laskowski-Jones, 2009). Thus tourniquets that occlude arterial blood flow distal to the injury are best reserved to control bleeding when hemorrhage is so severe that the risk to limb viability is justified to save a life. Internal hemorrhage is a more hidden complication that must be suspected in injured patients or those who present in a shock state.*

In a resuscitation situation, blood pressure can be quickly and easily estimated before a manual cuff pressure can be obtained by palpating for the presence or absence of peripheral and central pulses:

- Presence of a radial pulse: BP at least 80 mm Hg systolic
- Presence of a femoral pulse: BP at least 70 mm Hg systolic
- Presence of a carotid pulse: BP at least 60 mm Hg systolic

By the time hypotension occurs, compensatory mechanisms used by the body in an attempt to maintain vital signs in a shock state have been exhausted. Timely, effective intervention is critical to preserve life and vital organ function.

IV access is best achieved initially with insertion of large-bore (16-gauge) peripheral IV lines in the antecubital area (inside bend of the elbow). Additional access can be obtained via central veins in the femoral, subclavian, or jugular sites using large-bore (8.5 Fr) central venous catheters. Intraosseous access is an excellent initial approach for critically ill patients when veins cannot be rapidly accessed by the resuscitation team (see [Chapter 15](#) for discussion of intraosseous infusion therapy). Resuscitation solutions of choice are Ringer's lactate and 0.9% normal saline (NS). Fluids and blood products should be warmed before administration to prevent hypothermia. A good rule of thumb is to consider the need

for blood product administration in a hemorrhagic shock state when significant hypotension persists after infusion of 2 L of solution.

D: Disability

The disability examination provides a rapid baseline assessment of neurologic status. A simple method to evaluate level of consciousness is the “AVPU” mnemonic:

- A: Alert
- V: Responsive to voice
- P: Responsive to pain
- U: Unresponsive

Another common way of determining and documenting level of consciousness is the [Glasgow Coma Scale \(GCS\)](#), an assessment that scores eye opening, verbal response, and motor response. The lowest score is 3, which indicates a totally unresponsive patient; a normal GCS score is 15. Metabolic abnormalities (e.g., severe hypoglycemia), hypoxia, neurologic injury, and illicit drugs or alcohol can impair level of consciousness. Frequent reassessment is needed for rapid intervention in the event of neurologic compromise or deterioration.

E: Exposure

The final component of the primary survey is [exposure](#).

! NURSING SAFETY PRIORITY

Action Alert

Remove all clothing to allow for thorough assessment. Always *cut away* clothing with scissors (Laskowski-Jones, 2009):

- During resuscitation when rapid access to the patient's body is critical
- When manipulating a patient's limbs to remove clothing could cause further injury
- When thermal or chemical burns have caused fabrics to melt into the patient's skin

If evidence preservation is an issue, handle items per institutional policy. Evidence may include articles of clothing, impaled objects, weapons, drugs, and bullets. Emergency nurses are often called upon to provide testimony in court regarding their recall of the presentation and treatment of patients in the ED. Examples of types of cases in which evidence collection is vital are rape, elder abuse, domestic violence, homicide, suicide, drug overdose, and assault.

Once clothing is removed, hypothermia (body temperature less than or equal to 97° F [36° C]) poses a risk to injured patients, especially those with burns (Laskowski-Jones, 2009). Specifically, hypothermia complicates management of the injured patient by causing:

- Vasoconstriction
- Difficulty with venous access and arterial assessment
- Coagulopathy
- Increased bleeding
- Slowed drug metabolism

Interventions to prevent hypothermia are basic:

- Remove wet sheets or clothing.
- Cover the patient with blankets.
- Infuse only warm solutions and blood products.
- Set the room temperature at 75° to 80° F.
- Use devices such as heat lamps and warming blankets.

[Table 10-4](#) highlights the primary survey and associated resuscitation interventions.

TABLE 10-4 THE PRIMARY SURVEY AND RESUSCITATION INTERVENTIONS

PRIORITIES OF THE PRIMARY SURVEY	EXAMPLES OF SPECIFIC INTERVENTIONS
A: Airway/cervical spine	Establish a patent airway by positioning, suctioning, and oxygen as needed. Protect the cervical spine by maintaining alignment; use a jaw-thrust maneuver if there is a risk for spinal injury. If the Glasgow Coma Scale (GCS) score is 8 or less or the patient is at risk for airway compromise, prepare for endotracheal intubation and mechanical ventilation.
B: Breathing	Assess breath sounds and respiratory effort. Observe for chest wall trauma or other physical abnormality. Prepare for chest decompression if needed. Prepare to assist ventilations if needed.
C: Circulation	Monitor vital signs, especially blood pressure and pulse. Maintain vascular access using a large-bore catheter. Use direct pressure for external bleeding.
D: Disability	Evaluate the patient's level of consciousness (LOC) using the AVPU system and the GCS. Re-evaluate the patient's LOC frequently.
E: Exposure	Remove all clothing for a complete physical assessment. Prevent hypothermia (e.g., cover the patient with blankets, use heating devices, infuse warm solutions).

**NCLEX EXAMINATION CHALLENGE****Safe and Effective Care Environment**

A client is admitted to the ED with multiple stab wounds to his chest, abdomen, and arms. What is the nurse's priority upon admission to the ED?

- A. Check for bleeding from the stab wounds.
- B. Assess and maintain the client's airway.
- C. Start two large-bore IV lines.
- D. Assess the level of consciousness.

The Secondary Survey and Resuscitation Interventions

After the ED resuscitation team addresses the immediate life threats, other activities that the emergency nurse can anticipate include insertion of a gastric tube for decompression of

the GI tract to prevent vomiting and aspiration, insertion of a urinary catheter to allow careful measure of urine output, and preparation for diagnostic studies. The resuscitation team also performs a more comprehensive head-to-toe assessment, known as the **secondary survey**, to identify other injuries or medical issues that need to be managed or that might affect the course of treatment.

Disposition

The patient may be transported immediately to the operating room or interventional radiology suite directly from the ED, depending on the nature of the injury. When no immediate procedural intervention is indicated, patients are admitted to the trauma or critical care unit, step-down unit, or medical-surgical unit for continued management and nursing care based on the nature and severity of their injuries, as well as any other pre-existing medical conditions (e.g., liver disease, heart disease, cancer) that could complicate trauma care. However, if the facility does not have the resource capabilities to manage the injured patient, the physician arranges for transfer to a higher level of care.

Collaborate with the interdisciplinary team to address the trauma patient's complex health care needs, including early consultation with social services and the rehabilitation team. Coordinate with other support services as necessary, such as pastoral care, nutrition support, psychiatry, behavioral health specialists, and substance abuse counselors. Trauma centers are required to incorporate systems to identify patients with high-risk alcohol use (American College of Surgeons Committee on Trauma, 2006). An effective strategy is to implement an SBIRT (**s**creening, **b**rief **i**ntervention, and **r**eferral to **t**reatment) program in which interdisciplinary trauma team members, including nurses, are educated to assess patients for problem drinking. The typical interaction involves a brief, respectful conversation that offers feedback, advice, and motivation to reduce alcohol consumption (Barnard, 2009).

Consider the needs of family members in crisis and address them when planning nursing care. A trauma advanced practice nurse, if available, can help coordinate trauma care by offering clinical expertise, facilitating communication among caregivers, and serving as an educator for the patient, staff, and family (Mower-Wade & Pirrung, 2010). They can organize family meetings with the interdisciplinary team and arrange for necessary resources. If this resource is not available, a case manager or specially educated staff nurse may perform these functions.

GET READY FOR THE NCLEX® EXAMINATION!**KEY POINTS**

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Emergency departments (EDs) are fast-paced and often crowded environments where care occurs for patients across the life span with a variety of health problems.

- Vulnerable populations who present to the ED include patients who are uninsured (poor), homeless, and older adults.
- Anticipate that some of the most common reasons that patients seek ED care are chest pain, abdominal pain, difficulty breathing, injury, poisoning, headache, and fever.

GET READY FOR THE NCLEX® EXAMINATION! —cont'd

- When caring for ED patients, collaborate with the interdisciplinary ED team, which includes prehospital providers, physicians, nurses, specialty teams, and support staff.
- Use the best practices listed in [Chart 10-1](#) to maintain safety in the ED.
- Core competencies for the ED nurse include assessment, priority setting, knowledge, technical skills, and communication.
- The three-level triage model categorizes patients as emergent, urgent, and nonurgent (see [Table 10-2](#)). The Emergency Severity Index is a five-tier triage system that uses both acuity and the prediction of necessary resources to rapidly categorize the priority of patients.
- Trauma centers are categorized as Levels I through IV, based on their resource capabilities as listed in [Table 10-3](#).
- The mechanism of injury describes the manner in which the traumatic event occurred.
- The two most common injury-producing mechanisms are blunt trauma and penetrating trauma.
- Implement the steps of the primary survey and trauma resuscitation interventions outlined in [Table 10-4](#).
- Patient education as part of the discharge plan is an important part of ED nursing practice.

Psychosocial Integrity

- Provide support for patients who lose a loved one; consult with the psychiatric crisis team as needed.

Physiological Integrity

- Patients who are admitted to the ED are treated and stabilized before discharge. Patients may be discharged to their homes or inpatient facilities.
- About half of all older adults who visit the ED are admitted to the hospital.
- ED nurses are accountable for preventing or reducing risks to older adults while in the ED, such as falls, medication errors, pressure ulcers, and hospital-acquired infections. Communication with the older adult may be challenging if he or she has memory loss or develops acute delirium while in the ED.

Decision-Making Challenges
Audio Glossary

Key Points
Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Collaborate with the health care team when providing care for patients with common environmental emergencies.

Health Promotion and Maintenance

2. Identify community resources for patients with insect bites and snakebites.
3. Teach people at risk how to prevent heat-related and cold-related injuries, especially older adults.
4. Teach people at risk how to prevent arthropod bites and stings and snakebites.

Physiological Integrity

5. Assess patients at high risk for environmental emergencies.

6. Prioritize first aid/prehospital interventions for patients who have heat-related or cold-related injuries.
7. Prioritize first aid/prehospital interventions for patients who have arthropod bites.
8. Prioritize first aid/emergency care interventions for patients who have venomous snakebites.
9. Apply knowledge of pathophysiology to identify best practices for care of patients with environmental emergencies.
10. Develop an evidence-based plan of care for a patient who is allergic to bees and is stung.
11. Prioritize care for patients who have been struck by lightning.
12. Prioritize care for patients who survive a drowning incident.
13. Explain best practices for patients who are at risk for or experience altitude-related illnesses.

Recreational activities, as well as home and work responsibilities, make people of all ages leave their homes to go outdoors. However, seemingly harmless outside activities can have associated environmental risks, especially for older adults. Some risks, such as insect bites or stings, reptile bites, and environmental conditions, may also pose threats indoors. This chapter provides an overview of selected environmental emergencies, their initial emergency management (first aid), and acute care interventions. Illness and injury prevention strategies for nurses to incorporate into their own lifestyle and health teaching opportunities are also discussed.

HEAT-RELATED ILLNESSES

High environmental temperature (above 95° F) and high humidity (above 80%) are the most common environmental factors causing heat-related illnesses. These illnesses include heat exhaustion and heat stroke. Some of the most vulnerable, at-risk populations for these problems are:

- Older adults
- Blacks (more than whites)
- People who work outside, such as construction and agricultural workers (more men than women)

- Homeless people
- Illicit drug users (especially cocaine users)
- Outdoor athletes (recreational and professional)
- Members of the military who are stationed in countries with hot climates (e.g., Iraq and Afghanistan)

Older adults have less body fluid volume and can easily become dehydrated when exposed to excessive heat and humidity. Blacks experience heat-related illnesses more than whites, probably because of social disadvantages (e.g., cannot afford air-conditioning, poor housing).

A patient's health status can also increase the risk for heat-related illness, especially obesity, heart disease, fever, strenuous exercise, seizures, and all degrees of burns (even sunburn). In addition, the use of certain prescribed drugs such as beta-adrenergic blockers, angiotensin-converting enzyme (ACE) inhibitors, and diuretics increases the risk for heat-related illness (Auerbach et al., 2008).

HEALTH PROMOTION AND MAINTENANCE

Teach older adults before participating in any hot weather activity how to consider their risks and to take steps to eliminate or minimize them whenever possible. Ask them to have a family member, friend, or neighbor check on them several times each day to ensure that there are no signs of heat-related illness. [Chart 11-1](#) lists other essential heat-related illness prevention strategies for older adults, many of which apply to adults of any age.

HEAT EXHAUSTION

Pathophysiology

Heat exhaustion is a syndrome resulting primarily from dehydration. It is caused by heavy perspiration, as well as inadequate fluid and electrolyte intake during heat exposure over hours to days. Patients feel ill, and their clinical manifestations resemble the flu. Although not a true emergency condition, *if untreated, heat exhaustion can lead to heat stroke, a much more serious problem.*

CHART 11-1 NURSING FOCUS ON THE OLDER ADULT

Heat-Related Illness Prevention

- Avoid alcohol and caffeine.
- Prevent overexposure to the sun; use a sunscreen with an SPF of at least 30 with UVA and UVB protection.
- Rest frequently and take breaks from being in a hot environment. Plan to limit activity at the hottest time of day.
- Wear clothing suited to the environment. Lightweight, light-colored, and loose-fitting clothing is best.
- Pay attention to your personal physical limitations; modify activities accordingly.
- Take cool baths or showers to help reduce body temperature.
- Stay indoors in air-conditioned buildings, if possible.
- Ask a neighbor, friend, or family member to check on the older adult at least twice a day during a heat wave.

SPF, Sun protection factor; UVA, ultraviolet A; UVB, ultraviolet B.

PATIENT-CENTERED COLLABORATIVE CARE

In heat exhaustion, patients usually have flu-like symptoms with headache, weakness, nausea, and/or vomiting. Body temperature is not significantly elevated in this condition. The patient may continue to perspire despite dehydration.

! NURSING SAFETY PRIORITY

Action Alert

Assess the patient for orthostatic hypotension and tachycardia, especially the older adult who is predisposed to rapid dehydration. Older adults who are already dehydrated often experience acute confusion and are at risk for falls.

Ask the person experiencing heat exhaustion to immediately stop physical activity; move him or her to a cool place, and use cooling measures. Effective cooling measures include placing cold packs on the neck, chest, abdomen, and groin; soaking the person in cool water; or fanning him or her while spraying water on the skin (Auerbach et al., 2008). Remove any constrictive clothing. Provide an oral rehydrating solution such as a sports drink. *Do not give salt tablets*—they can cause stomach irritation, nausea, and vomiting. If these signs and symptoms persist, call an ambulance to transport the patient to the hospital.

In the clinical setting, monitor vital signs. Rehydrate the patient with IV 0.9% saline solution if nausea or vomiting persists. Draw blood for serum electrolyte analysis. Hospital admission is indicated only for patients who have other health problems that are worsened by the heat-related illness or for those with severe dehydration. The management of hypovolemic dehydration is discussed in more detail in [Chapter 13](#).

HEAT STROKE

Pathophysiology

Heat stroke is a *true medical emergency* in which body temperature may exceed 104° F (40° C). It has a high mortality rate if not treated in a timely manner. The victim's heat regulatory mechanisms fail and cannot adjust for a critical elevation in body temperature (Laskowski-Jones, 2010). If the condition is not treated or the patient does not respond to treatment, organ dysfunction and death can result. In their cohort study of 16 emergency departments, Hausfater et al. (2010b) found that nine factors help predict mortality in patients admitted to emergency departments with non-exertional heat stroke (see Evidence-Based Practice box on p. 138).

The two major types of heat stroke are exertional and classic. **Exertional heat stroke** has a sudden onset and is often the result of strenuous physical activity in hot, humid conditions. Not being used to hot weather and wearing clothing too heavy for the environment are common contributing factors. **Classic heat stroke**, also referred to as non-exertional heat stroke, occurs over a period of time as a result of chronic exposure to a hot, humid environment, such as a home without air-conditioning in the high heat of the summer. It generally affects ill and older adults and causes several hundred deaths in the United States every year. The risk

EVIDENCE-BASED PRACTICE

What Factors Predict Who Will Develop Nonexertional Heat Stroke?

Hausfater, P., Megarbane, B., Dautheville, S., Patzak, A., Andronikof, M., Andre, S., et al. (2010). Prognostic factors in non-exertional heatstroke. *Intensive Care Medicine*, 36, 272-280.

Heat-related illnesses are often medical emergencies that can lead to death. The authors presented findings of a large multi-center observational cohort study of 1456 patients who were admitted to 16 emergency departments (EDs) in teaching hospitals during heat waves. The mean age of the sample was 79 years, and 391 of them were critically ill on admission. All of the study patients had an elevated core body temperature. The survival rate for the study sample was only 57% at 1 year after diagnosis.

On retrospective review of the patients' charts, it was found that nine factors negatively influenced survival rates. They included an age older than 80 years, body temperature of over 104° F (40° C), systolic blood pressure less than 100 mm Hg, Glasgow Coma Scale score of less than 12, presence of cancer and/or cardiac disease, previous treatment with diuretics, living in an institution, and transported to the ED by ambulance.

Level of Evidence: 4

This study is a nonexperimental or descriptive cohort study, but it used a large sample size in multiple emergency departments. Random assignment or comparison of two groups was not appropriate for answering the research question.

Commentary: Implications for Practice and Research

The results of this study indicate that older, institutionalized patients with cardiac disease or cancer and heat stroke have a high risk for not surviving a year after the heat-related illness. The major nursing implication from this study is that more emphasis on preventing heat-related illnesses in institutionalized patients is needed, particularly if they are older than 80 years. Nurses are in a key position to advocate for these patients and to implement interventions that can help prevent heat stroke. Early detection and treatment also are needed. [Chart 11-1](#) lists best practices for decreasing the risk for heat-related illnesses in older adults.

CHART 11-2 KEY FEATURES

Heat Stroke

- Body temperature more than 104° F (40° C)
- Hot and dry skin; may or may not perspire
- Mental status changes, such as:
 - Acute confusion
 - Bizarre behavior
 - Anxiety
 - Loss of coordination
 - Hallucinations
 - Agitation
 - Seizures
 - Coma
- Vital sign changes, including:
 - Hypotension
 - Tachycardia
 - Tachypnea (increased respiratory rate)
- Electrolyte imbalances, especially sodium and potassium
- Decreased renal function (oliguria)
- Coagulopathy (abnormal clotting)
- Pulmonary edema (crackles)

factors for heat stroke are similar to those for heat exhaustion.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Victims of heat stroke have a profoundly elevated body temperature (above 104° F [40° C]). *Although the patient's skin is hot and dry, the presence of sweating does not rule out heat stroke—people with heat stroke may continue to perspire.*

Mental status changes occur as a result of thermal injury to the brain. Manifestations can include confusion, bizarre behavior, seizures, or even coma ([Chart 11-2](#)). Vital sign abnormalities may include hypotension, tachycardia, and tachypnea. Recent research demonstrates that cardiac troponin I (cTnI) is frequently elevated during non-exertional

heat-related illnesses. A severe increase (>1.5 ng/mL) indicates severe myocardial damage and decreases the chance of patient survival 1 year after the event (Hausfater et al., 2010a).

Complications of classic heat stroke include multiple organ dysfunction syndrome (MODS), renal impairment, electrolyte and acid-base disturbances, coagulopathy (abnormal clotting), pulmonary edema, and cerebral edema (Johnson et al., 2008). Any of these problems can lead to death and are described in detail elsewhere in this book.

INTERVENTIONS

Coordinate care with the health care team to recognize and treat immediately and aggressively to achieve optimal patient outcomes. [Chart 11-3](#) lists evidence-based emergency care of patients with heat stroke.

First Aid/Prehospital Care

Do not give food or liquid by mouth because vomiting and aspiration are risks in patients with neurologic impairment, especially those older than 65 years. Immediate medical care using advanced life support is essential.

! NURSING SAFETY PRIORITY**Critical Rescue**

After ensuring that the patient has a patent airway, effective breathing, and adequate circulation, use rapid cooling as the first priority for care. Methods for rapidly cooling include:

- Removing clothing
- Placing ice packs on the neck, axillae, chest, and groin
- Immersing the victim in cold water
- Wetting the patient's body with tepid water and then fanning rapidly to aid in cooling by evaporation

Drenching the victim with large amounts of icy water may be the fastest, most effective means to reduce core body temperature (Auerbach, 2009).

Hospital Care

The first priority for collaborative care is to monitor and support the patient's airway, breathing, and circulatory status. Provide

CHART 11-3 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Emergency Care of the Patient with Heat Stroke**At the Scene**

- Ensure a patent airway.
- Remove the patient from the hot environment (into air-conditioning or into the shade).
- Remove the patient's clothing.
- Pour or spray water on the patient's body and scalp.
- Fan the patient (not only the person providing care, but all surrounding people should fan the patient with newspapers or whatever is available).
- If ice is available, place ice in cloth or bags and position the packs on the patient's scalp, in the groin area, behind the neck, and in the armpits.
- Get the patient to the nearest emergency department.

At the Hospital

- Give oxygen by mask or nasal cannula.
- Start at least one IV with a large-bore needle or cannula.
- Administer normal saline (0.9% sodium chloride) as rapidly as possible, using cooled solutions if available.

- Use a cooling blanket.
- Do not give aspirin or any other antipyretics.
- Insert a rectal probe to measure core body temperature continuously, or use a rectal thermometer and assess temperature every 15 minutes.
- Insert a Foley catheter.
- Monitor vital signs frequently as clinically indicated.
- Obtain baseline laboratory tests as quickly as possible: serum electrolytes, cardiac enzymes, liver enzymes, and complete blood count (CBC).
- Assess arterial blood gases.
- Administer muscle relaxants (benzodiazepines) if the patient begins to shiver.
- Measure urine output and specific gravity to determine fluid needs.
- Slow cooling interventions when core body temperature is reduced to 102° F (39° C); stop cooling when rectal temperature is 100° F (37.8° C).
- Obtain urinalysis, and monitor urine output.

high-concentration oxygen therapy, start several IV lines with 0.9% saline solution, and insert a urinary catheter. Continue aggressive interventions to cool the patient until the rectal temperature is 100° F (37.8° C) (Auerbach, 2009). External continuous cooling methods include using cooling blankets and applying ice packs in the axilla and groin and on the neck and head. Internal cooling methods may include iced gastric and bladder lavage. Use a continuous core temperature-monitoring device (e.g., rectal or esophageal probe) or a temperature-monitoring urinary bladder catheter to prevent hypothermia.

If shivering occurs during the cooling process, give a parenteral benzodiazepine such as diazepam (Valium). Chlorpromazine (Thorazine) is an alternative agent. Because seizure activity can further elevate body temperature, be sure to have an IV benzodiazepine immediately available. Once the patient is stabilized, admission to a critical care unit is usually needed to monitor for complications such as multi-system organ dysfunction syndrome and severe electrolyte imbalances; these problems can lead to death.

**NCLEX EXAMINATION CHALLENGE****Physiological Integrity**

An older client with heat stroke is being cooled with a cooling blanket and ice packs under her arms and behind her neck. What assessment indicates to the nurse that the cooling process is effective?

- The client is alert and oriented.
- The client states that she feels cooler.
- The client's temperature is 100° F.
- The client's urinary output is 30 mL/hr.

SNAKEBITES

Although most snake species are nonvenomous (nonpoisonous) and harmless, there are two families of poisonous snakes in North America: pit vipers (*Crotalidae*) and coral snakes (*Elapidae*).

FIG. 11-1 Southern copperhead (*Agkistrodon contortrix*) has markings that make it almost invisible when lying in leaf litter.

FIG. 11-2 Cottonmouth water moccasin (*Agkistrodon piscivorus*). The open-mouthed threat gesture is characteristic of this semiaquatic pit viper.

Pit vipers are named for the characteristic depression between each eye and nostril that serves as a heat-sensitive organ for locating warm-blooded prey. They include various species of rattlesnakes, copperheads, and cottonmouths and account for the majority of the poisonous snakebites in the United States (Figs. 11-1 and 11-2).

Coral snakes are found from North Carolina to Florida and in the Gulf states through Texas and the southwestern

CHART 11-4 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Snakebite Prevention

- Do not keep venomous snakes as pets.
- Be extremely careful in locations where snakes may hide, such as tall grass, rock piles, ledges and crevices, woodpiles, brush, boxes, and cabinets. Snakes are most active on warm nights.
- Don protective attire such as boots, heavy pants, and leather gloves. When walking or hiking, use a walking stick or trekking poles.
- Inspect suspicious areas before placing hands and feet in them.
- Do not harass any snakes you may encounter. Striking distance is at least the length of the snake, and often longer. Even young snakes pose a threat; they are capable of envenomation from birth.
- Be aware that newly dead or decapitated snakes can inflict a bite for up to an hour after death because of persistence of the bite reflex.
- Avoid transporting the snake with the victim to the medical facility for identification purposes, unless the snake can be placed in a sealed container.

United States. They have broad bands of red and black rings, separated by yellow or cream rings. These nonaggressive snakes have short, fixed fangs and inject highly neurotoxic venom into prey.

Most snakes fear humans and attempt to avoid contact with them. Sudden, unexpected confrontations at close range often lead to defensive strikes. Awareness is the key to snakebite prevention.

HEALTH PROMOTION AND MAINTENANCE

Chart 11-4 provides common-sense actions to avoid being bitten by a poisonous snake. Teach people who own snakes to follow these precautions. Remind them that snakebites can be life threatening.

NORTH AMERICAN PIT VIPERS

North American pit vipers can be differentiated from harmless snakes by these key anatomic features:

- A heat-sensing “pit”
- A triangular head that indicates the presence of venom glands and elliptical pupils
- Two retractable, curved fangs that have canals for venom flow
- Up to three sets of developing “replacement” fangs behind the primary fangs

Unlike copperheads and cottonmouths, rattlesnakes also have interlocking horny rings in their tails that vibrate and serve as a characteristic warning signal. Pit vipers can regulate the amount of venom flow through their fangs, depending, in part, on the size of the prey. The amount of venom injected in bites to humans varies. A bite might actually be “dry,” meaning there is no **envenomation** (venom injection), yet there are distinctive fang marks on the patient. In contrast, “harmless” snakes do not have venom glands or fangs but can bite and leave skin marks.

Pathophysiology

When providing emergency care to a victim of snakebite, determine if the venom has been injected into the body. The primary functions of venom are to immobilize, kill, and aid in digestion of prey. Therefore venom causes local and systemic toxic effects. The enzymes in venom break down human tissue proteins, alter membrane integrity, and impair blood clotting. The pathophysiologic effects of pit viper envenomation can lead to local tissue necrosis, massive tissue swelling, intravascular fluid shifts and hypovolemic shock, pulmonary edema, renal failure, hemorrhagic complications from disseminated intravascular coagulation (DIC), and death. These complications are discussed elsewhere in this book.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

The clinical manifestations of venom release are based on the type and amount of venom injected; the bite location; and the age, size, and health status of the victim. Puncture wounds in the skin are a key local sign of pit viper envenomation. One or more puncture wounds may be present, depending on how many fangs the snake has and how many times the snake struck the patient. Severe pain, swelling, and redness or **ecchymosis** (bruising) in the area around the bite are common. Hours later, vesicles or hemorrhagic bullae may form. Systemic responses to venom must be distinguished from the effects of anxiety and panic related to being bitten by a snake. Commonly reported complaints include a minty, rubbery, or metallic taste in the mouth and tingling or paresthesias of the scalp, face, and lips. Other effects include muscle **fasciculations** (twitching) and weakness, nausea, vomiting, hypotension, seizures, and **coagulopathy** (clotting abnormalities) or DIC. If the bite site does not show evidence of local tissue swelling or redness within 8 hours, systemic effects are less likely to develop.

INTERVENTIONS

First Aid/Prehospital Care

First aid interventions for snakebite should begin in the field and can improve the victim's outcome.

! NURSING SAFETY PRIORITY

Critical Rescue

The first priority is to move the person to a safe area away from the snake and encourage rest to decrease venom circulation. Next, remove jewelry and constricting clothing before swelling worsens.

Immobilizing the affected extremity in a position of function with a splint helps limit the spread of the venom. Maintain the extremity at the level of the heart (Auerbach et al., 2008). Keep the person warm, and provide calm reassurance. Do not offer any alcohol because it can cause the venom to spread through vasodilation (Bledsoe et al., 2009). *Do not incise or suck the wound, apply ice to it, or use a tourniquet!*

Hospital Care

Acute care in a hospital is required as soon as possible because envenomation is a medical emergency. Supportive care includes

supplemental oxygen, two large-bore IV lines, and infusion of crystalloid fluids such as normal saline solution or Ringer's lactate solution. Apply continuous cardiac and blood pressure monitoring equipment to quickly detect clinical deterioration. Because venom can cause severe pain at the bite site, opioids are indicated. Provide tetanus prophylaxis and wound care as part of the collaborative plan of care.

Severe pit viper bites cause coagulopathy and promote hemorrhage and tissue destruction. Along with typical baseline laboratory studies, anticipate obtaining specimens for a coagulation profile, complete blood count (CBC), creatine kinase (CK), type and crossmatch for possible blood transfusion, and urinalysis. An electrocardiogram (ECG) is necessary to detect evidence of myocardial ischemia or other cardiac abnormalities.

Obtain pertinent patient history related to the event, including a full description of the snake's appearance, the time the bite occurred, prehospital interventions, and any past incidence of snakebite or antivenom use. To accurately assess the development of tissue edema at the bite site, measure and record the circumference of the bitten extremity every 15 to 30 minutes.

Venom potency varies. Not all snakebite victims need antivenom administration. The decision whether or not to give antivenom is based on the severity of the snakebite. [Table 11-1](#) classifies envenomation severity. *Contact the regional poison control center so that toxicologists can provide specific advice for antivenom dosing and medical management.*

The newest and safest antivenom for pit viper bites is Crotalidae Polyvalent Immune Fab (CroFab), which is derived from sheep (ovine). This drug consists of specific antibody fragments of immunoglobulin G (IgG) that bind, neutralize, and redistribute toxins in pit viper venom so that they may be removed from the patient's body (Schaeffer & Badillo, 2009). Unlike the older antivenoms that were derived from horse serum, serum sickness rarely occurs after IV CroFab administration. [Serum sickness](#) is a type III hypersensitivity reaction that develops within 3 to 21 days, first as a skin rash with progression to fever, joint pain, and [pruritus](#) (itching). Although mild to moderate allergic reactions such as pruritus

and [urticaria](#) (hives) can occur, anaphylaxis is rare. If the patient has a known hypersensitivity to papain or papaya, which is used during the manufacturing process, CroFab is contraindicated unless the benefits are believed to outweigh the risks (Protherics, Inc., 2008). Give CroFab cautiously to patients who have:

- A previous allergic reaction to antivenom therapy
- A hypersensitivity to bromelain (a pineapple-derived enzyme) or sheep protein
- Prior CroFab therapy for a past envenomation (patients can become sensitized to the foreign sheep protein)
- Pregnancy
- Sensitivity to mercury-containing products (the antivenom contains mercury)

CroFab should be given to patients as soon as possible, with the optimal timing within 6 hours of the bite (Protherics, Inc., 2008). The recommended initial IV dose is 4 to 6 vials infused over 60 minutes. During the first 10 minutes, the infusion should be slow (25-50 mL/hr). Monitor the patient closely for an allergic reaction (e.g., hives, rash, difficulty breathing). If symptoms are not effectively controlled with the first dose, an additional 4 to 6 vials are recommended. Once the symptoms are under control, 2 more vials of CroFab are administered every 6 hours for a total of 18 hours of administration (Protherics, Inc., 2008).

CORAL SNAKES

Pathophysiology

North American coral snakes are found in the southeastern and southwestern United States ([Fig. 11-3](#)). These snakes burrow into the ground and are nonaggressive. Coral snakes account for less than 1% of venomous snakebites in the United States (Norris, 2008). Their ability to inject venom is less efficient than that of the pit vipers. Their maxillary fangs are small and fixed in an upright position. Most bites occur when people attempt to handle the snake. Coral snake venom has two toxins: a nerve toxin and a muscle toxin. The amount of venom in an adult coral snake is enough to kill an adult.

Coral snakes can be recognized by bands of black, red, and yellow that circle around the body of the snake. If a black

TABLE 11-1 GRADES OF PIT VIPER ENVENOMATION

ENVENOMATION	CHARACTERISTICS
None	Fang marks, but no local or systemic reactions
Minimal	Fang marks, local swelling and pain, but no systemic reactions
Moderate	Fang marks and swelling progressing beyond the site of the bite; systemic signs and symptoms, such as nausea, vomiting, paresthesias, and hypotension
Severe	Fang marks present with marked swelling of the extremity, subcutaneous ecchymosis, severe symptoms, including manifestations of coagulopathy

From Auerbach, P.S., Donner, H.J., & Weiss, E.A. (2009). *Field guide to wilderness medicine* (3rd ed.). St. Louis: Mosby.

FIG. 11-3 Sonoran coral snake (*Micruroides euryxanthus*) is also known as the *Arizona coral snake*. No documented fatality has followed a bite by this species.

band lies between the red and yellow bands, the snake is often nonvenomous. Several harmless species closely resemble the coral snake. A helpful memory aid for identifying coral snakes is “red on yellow can kill a fellow” and “red and black, venom lack.” *Be aware that this saying applies only to coral snakes found in the United States!*

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Manifestations of coral snake envenomation are the result of its neurotoxic properties. The physiologic effect is to block neurotransmission, which produces ascending paralysis, reduced perception of pain, and, ultimately, respiratory paralysis (Wozniak et al., 2006). Unlike the pain from pit viper bites, pain at the coral snakebite site may be only mild and transient. The venom is spread via the lymphatic system, but swelling is unlikely. Fang marks may be difficult to find because of the coral snake’s small teeth. The toxic effects of coral snake venom also may be delayed up to 12 to 18 hours after a bite but then produce rapid clinical deterioration. Early signs and symptoms are nausea, vomiting, headache, pallor, and abdominal pain. Assess for neurologic manifestations, such as paresthesias (painful tingling), numbness, and mental status changes, as well as cranial nerve and peripheral nerve deficits. Total flaccid paralysis may occur later, and the patient may have difficulty speaking, swallowing, and breathing. Clotting changes do not occur.

Respiratory problems and cardiovascular collapse can occur in severe cases (Norris, 2008). Arterial blood gas analysis reveals respiratory insufficiency. The muscle toxin in the venom can cause an elevation in creatine kinase (CK) levels from muscle breakdown and produce **myoglobinuria** (release of muscle myoglobin into the urine). Despite these clinical effects, death is rare if the patient receives timely management.

INTERVENTIONS

First Aid/Prehospital Care

Because several varieties of harmless snakes resemble the coral snake, the first priority, if possible, is to identify the snake as a coral snake. *However, if the snake cannot be positively identified, the victim should be treated as if venom has been injected.* Because coral snake venom does not destroy tissue, the field treatment to limit the spread of venom includes the use of pressure immobilization techniques (Auerbach et al., 2008). The affected extremity is encircled snugly with an elastic bandage or roller gauze dressing to impede lymphatic flow and then splinted (Wozniak et al., 2006). *This compression bandage must not be so tight that it impairs arterial flow. It should not be removed until the victim is managed at an acute care facility* (Norris, 2008).

Hospital Care

Once in an acute care setting, patients who have had an actual or potential coral snake envenomation will have continuous cardiac, blood pressure, and pulse oximetry

monitoring and are admitted to a critical care unit. Prepare to provide aggressive airway management via endotracheal intubation if respiratory insufficiency or severe neurologic impairment occurs. Aspiration of secretions is a significant risk for this patient.

Early antivenom administration is recommended (Auerbach et al., 2008). The onset of symptoms after coral snake bites can be delayed but can persist for a week in spite of treatment (Norris, 2008). The antivenom for the North American coral snake is Antivenin *Micrurus fulvius* (Wyeth). However, this drug is no longer in active production by any drug manufacturer; only very limited supplies are available. *Contact the regional poison control center immediately for specific advice on antivenom administration and patient management.* The same precautions are applied when administering coral snake antivenom as with Crotalidae (pit viper) antivenom.

! NURSING SAFETY PRIORITY

Drug Alert

The most significant risk to the victim is an anaphylactic response to the antivenom. Therefore ensure that the patient’s IV lines are patent and that emergency drugs (e.g., epinephrine, antihistamines, steroids) and resuscitation equipment are immediately available.

A patient may survive a coral snake bite without antivenom but may require prolonged mechanical ventilation and supportive care (Norris, 2008).

ARTHROPOD BITES AND STINGS

Arthropods include spiders, scorpions, bees, and wasps. Unlike snakes, almost all species of spiders are venomous to some degree—most are not harmful to humans either because their mouth is too small to pierce human skin or the quantity or quality of their venom is inadequate to produce major health problems. Brown recluse and black widow spiders, scorpions, bees, and wasps are examples of venomous arthropods that can cause toxic reactions in humans. **Chart 11-5** lists actions that help prevent arthropod bites and stings.

BROWN RECLUSE SPIDER

Pathophysiology

Brown recluse spiders are known for producing bites that result in skin ulcers. Also known as “fiddlebacks” or “violin spiders,” they are medium-size spiders that are light brown and have a dark brown, fiddle-shaped mark that extends from their eyes down their back (**Fig. 11-4**). Like their name implies, brown recluse spiders are shy and hide in areas that are dark and secluded, such as boxes, closets, basements, sheds, and garages. Most indoor bites occur when people are sleeping, reaching into boxes or closets, or donning clothing that contains the spider. Few people ever see the spider that bit them. The only evidence may be a skin lesion; a necrotic wound; or, less often, systemic effects from the injected toxin, commonly referred to as **loxoscelism**.

CHART 11-5 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Arthropod Bite/Sting Prevention

- Wear protective clothing, including gloves and shoes, when working in areas known to harbor venomous arthropods, such as spiders, scorpions, bees, and wasps.
- Cover garbage cans. Bees and wasps are attracted to uncovered garbage.
- Use screens in windows and doors to prevent flying insects from entering buildings.
- Inspect clothing, shoes, and gear for insects before putting on these items.
- Shake out clothing and gear that have been on the ground to prevent arthropod “stowaways” and inadvertent bites and stings.
- Consult an exterminator to control arthropod populations in and around the home. Eliminating insects that are part of the arthropod’s food source may also limit their presence.
- Identify nesting areas such as yard debris and rock piles; remove them whenever possible.
- Do not place unprotected hands where the eyes cannot see.
- Avoid handling insects or keeping them as “pets.”
- Do not swat insects, wasps, and Africanized bees because they can send chemical signals that alert others to attack.
- Carry prescription epinephrine preparations and antihistamines if known to be allergic to bee and wasp stings.

FIG. 11-4 Brown recluse spider (*Loxosceles reclusa*).

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Brown recluse spider venom causes cell damage. The bite may be described as painless or stinging to sharp and painful. Some victims are unaware that they were bitten until intense local aching and pruritus develop over minutes to hours. The central bite site may appear as a bleb or vesicle surrounded by edema and erythema, which may expand over the course of hours as the toxin spreads to surrounding tissues. The center of the bite becomes bluish purple. Some people have few or no tissue changes and therefore do not require medical attention.

For other people who are bitten, over the next 1 to 3 days the central part of the wound becomes dark and necrotic (Fig. 11-5). **Eschar** (a necrotic, leathery covering over the wound) eventually forms. The combination of these tissue changes is often referred to as the classic “red, white, and blue sign” that is associated with severe brown recluse spider bites.

FIG. 11-5 Brown recluse spider bite after 24 hours, with central ischemia and rapidly advancing cellulitis.

When the eschar sloughs, an open wound or ulcer can remain for weeks to months. In rare cases, some patients may also have manifestations of systemic toxicity to brown recluse spider bites. These can include a rash, fever, chills, nausea, vomiting, malaise, and joint pain. In the worst cases, hemolytic reactions, renal failure, pulmonary edema, cardiovascular collapse, and death can occur.

INTERVENTIONS

First Aid/Prehospital Care

The basic first aid for a brown recluse spider bite is to apply ice intermittently during the first 4 days after the bite (Auerbach et al., 2008). Ice helps decrease the enzyme activity of the venom and may limit tissue swelling and necrosis. *Do not use heat because it increases the enzyme activity and potentially worsens the wound.* Recommended actions include elevation of the affected extremity, local wound care, and rest.

Hospital Care

Supportive care and ongoing monitoring for complications meet the needs of most patients with a brown recluse spider bite. For patients with wounds that appear infected, a topical antiseptic and sterile dressing are necessary. Antibiotics may also be required.

A surgeon evaluates patients whose wounds require interventions beyond conservative management. Débridement (removal of necrotic tissue) and skin grafting may be required to promote healing in severe wounds. In all cases, provide tetanus prophylaxis. Where available, collaborate with a wound specialist nurse.

A small number of patients experience severe systemic complications (loxoscelism). Manifestations include:

- Fever and chills
- Nausea and vomiting
- Renal failure
- **Hemolytic anemia** (anemia caused by destruction of red blood cells)
- **Thrombocytopenia** (decreased platelets)
- Disseminated intravascular coagulation (DIC)
- Death

These problems are discussed elsewhere in this text. Critical care management, including aggressive hydration, blood transfusions, and supportive therapies, is required to prevent further deterioration and promote recovery.

BLACK WIDOW SPIDER

Pathophysiology

Black widow spiders can be found in every state in the United States except Alaska. They can inflict deadly bites and are found in cool, damp environments like outdoor log piles, vegetation, and rocks. They also commonly inhabit barns, sheds, and garages. The female spider is best identified by her shiny black color and the red hourglass pattern on her abdomen. Male spiders are smaller in size and lighter in color with white and gray markings. The hourglass pattern is faint in males. Black widow spiders carry neurotoxic venom. Bites to humans are usually defensive when the spider is at risk for being crushed.

The initial bite of a black widow spider ranges from nearly painless to sharply painful. Typically, the person notices a tiny papule or small, red punctate mark. Some people have intense pain, which seems out of proportion to the lesion. In many cases, the symptoms do not progress beyond a local reaction in the area of the bite site. If systemic signs and symptoms do occur, they generally develop within 1 hour and involve the neuromuscular system.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Black widow spider venom produces a syndrome known as **latrodectism**, in which the venom causes neurotransmitter release from nerve terminals. Severe abdominal pain, muscle rigidity and spasm, hypertension, and nausea and vomiting are common. The problem may be incorrectly diagnosed as an acute abdomen, and surgical consultation may be considered because of the clinical features similar to peritonitis (Weinstein et al., 2009). Muscle spasms involve the large muscles of the abdomen, back, and limbs. Other problems include facial edema, **ptosis** (eyelid drooping), diaphoresis, weakness, increased salivation, respiratory difficulty from excessive secretions, fasciculations (twitching), and **paresthesias** (painful tingling or numbness). The effects of the bite are self-limited and generally resolve in a few days. *However, older adults with other health problems like cardiovascular disease are at much higher risk for complications.*

INTERVENTIONS

First Aid/Prehospital Care

! NURSING SAFETY PRIORITY

Action Alert

The priority intervention for a black widow spider bite in the prehospital setting is to apply an ice pack because cold application decreases the action of the neurotoxin.

Monitor the person for evidence of systemic toxicity as described in the previous Assessment section. If this problem occurs, support the patient's airway, breathing, and circulation. Patients should be transported to a medical facility as soon as possible for advanced life support care.

Hospital Care

In the emergency department, closely monitor vital signs, with special attention to blood pressure and respiratory function. Supportive therapy in the hospital includes administration of opioid pain medication and muscle relaxants such as diazepam (Valium). Provide tetanus prophylaxis as needed. Observe the patient for seizures related to a rapidly rising blood pressure (Auerbach et al., 2008). For some patients, antihypertensive agents are needed. Although relapses may occur, the patient usually recovers within a week.

Less often, pulmonary edema, uncontrollable hypertension, seizures, respiratory arrest, and shock occur. These patients require critical care management. Antivenom is available for black widow spider bites. Although it can cause anaphylaxis and serum sickness, antivenom is considered effective in treating severe reactions (Weinstein et al., 2009). The drug is also given to pregnant women because they may have uterine contractions from a black widow spider bite that can lead to a premature delivery (Auerbach, 2007). The regional poison control center provides information about antivenom dosing and management for women who are pregnant.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

A client is bitten on the leg by a black widow spider and needs immediate intervention by his friend who is a nurse. What is the nurse's priority action?

- A. Take the client to the hospital immediately.
- B. Apply moist heat to promote healing.
- C. Elevate the affected extremity above the heart.
- D. Apply ice to the bite area to decrease neurotoxicity.

SCORPIONS

Pathophysiology

Scorpions are found in many states within the United States although not typically in the Midwest or New England. However, stings are always possible when people keep scorpions as pets or when scorpions are accidentally transported in baggage and packaging. Unlike spiders that envenom their prey by inflicting a bite, scorpions inject venom through a stinging apparatus on their tail. Most scorpion stings produce a mild reaction characterized by local pain, inflammation, and mild systemic symptoms. These effects are usually self-limiting and best treated by analgesics, supportive management, and basic wound care.

One species of scorpion found in the southwestern United States that can inflict a sting associated with a potentially fatal systemic response is the bark scorpion (Fig. 11-6). It is often found in trees and woodpiles and around debris. Humans are usually stung when the scorpion gets into clothing, shoes, blankets, and personal items left on the ground.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Because bark scorpion venom is neurotoxic, clinical manifestations result from cranial nerve and/or skeletal muscle

FIG. 11-6 *Centruroides exilicauda* (*C. sculpturatus*), the bark scorpion of Arizona.

involvement. The sting site may or may not show evidence of the venom release. There may be no redness or other obvious sign of inflammation. Gentle tapping at the potential sting site causing increased pain is associated with a bark scorpion sting (Suchard, 2007). The severity of the reaction varies from local pain to severe systemic manifestations, such as high fever, hypertension, GI disorders, tachycardia, cardiac dysfunction, pulmonary edema, and nervous system involvement. In rare cases, death can occur.

Symptoms usually begin immediately after the sting and can reach a crisis level within 12 hours. Recovery occurs gradually. Pain and paresthesias can remain for up to 2 weeks (Suchard, 2007).

INTERVENTIONS

The first priority of patient management is vital sign assessment and continuous monitoring for several hours in a hospital emergency department or critical care unit. As symptoms worsen, the patient may develop respiratory failure and need intubation and mechanical ventilation.

Provide supplemental oxygen and IV fluid replacement immediately. Apply an ice pack to the sting site to control pain. Give analgesic and sedative agents with caution in the non-intubated, spontaneously breathing patient. Potent opioids, benzodiazepines, and barbiturates can cause loss of airway reflexes and precipitate respiratory failure. Fever is treated with acetaminophen (Tylenol) and application of a cooling blanket as needed. Because scorpion stings produce a puncture wound, provide tetanus prophylaxis and basic wound care with an antiseptic agent. *Contact the poison control center as soon as possible to assist with patient management, particularly in regard to use of pharmacologic agents for scorpion stings.*

BEEES AND WASPS

Pathophysiology

Bees and wasps are also venomous arthropods. Stings can produce a wide range of reactions from discomfort at the sting site to severe pain, multi-system problems, and life-threatening anaphylaxis in allergic people. Bumblebees, hornets, and wasps are capable of stinging repeatedly when

disturbed. They have a smooth stinger that typically does not become lodged in the victim. Only the honeybees can sting just once. When a honeybee stings a person, the stinger and venom sac pull away from the bee. The bee dies, but venom injection continues because the stinger and sac remain in the victim.

“Africanized” bees, also called “killer bees,” are a very aggressive species found in the southwestern states that are known to attack in groups and can remain agitated for several hours. People under attack should attempt to outrun the bees, if possible, and keep their mouth and eyes protected from the swarm. A person should never go into a body of water because the bees will attack when he or she comes up for air. When a person sustains multiple stings, reactions are more severe and may be fatal because multiple venom doses have cumulative toxic effects.

Health Promotion and Maintenance

Chart 11-5 lists actions that may help prevent arthropod bites and stings.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

The person who is stung by a bee or wasp first has a local reaction of immediate pain and a wheal-and-flare skin reaction. For some people, swelling can be extensive and involve an entire limb or body area. Systemic effects can then develop based on the venom load and the person’s sensitivity to the venom. These effects may include generalized edema, nausea, vomiting, and diarrhea and are reactions to the toxic effects of the venom itself, not necessarily an allergic reaction. Other toxic venom effects include destruction of red and white blood cells and platelets, damage to the blood vessel walls, acute renal failure, liver injury, and cardiac dysrhythmias (Mitchell, 2006).

If the patient has an *allergy to the venom*, then **urticaria** (hives), pruritus (itching), and swelling of the lips and tongue may occur. An allergic response can rapidly progress to an anaphylactic reaction in highly sensitive patients. **Anaphylaxis** is a life-threatening allergic response and is evidenced by respiratory distress with bronchospasm and laryngeal edema, hypotension, deterioration in mental status, and cardiac dysrhythmias. *This type of reaction constitutes a true medical emergency that is imminently life threatening and may lead to cardiac arrest.* Realize that initially it may be impossible to distinguish an allergic reaction from a toxic venom reaction because they both can cause the same types of early signs and symptoms.

INTERVENTIONS

First Aid/Emergency Care

Basic emergency care for bee and wasp stings includes quick removal of the stinger (if present) and application of an ice pack (Laskowski-Jones, 2010). Tweezers formerly were avoided for stinger removal because it was believed that pinching the stinger would cause additional venom to be injected. However, this concern appears to be unfounded (Auerbach, 2009). The stinger is best removed with tweezers

or by gently scraping or brushing it off with the edge of a knife blade, credit card, or needle. The method used to remove the stinger is not as important as the speed of removal (Auerbach, 2009).

Advanced prehospital emergency care interventions are prioritized to ensure that airway, breathing, and circulation are maintained. First, determine whether the patient has a history of allergic reactions to bee stings and whether he or she has an epinephrine kit, also called a “bee kit.” These kits may also contain an antihistamine tablet. If the patient has a severe allergic reaction with wheezing, facial swelling, and respiratory distress, epinephrine is given immediately. Allergic adult patients typically carry an EpiPen. This device allows quick and simple epinephrine administration in an emergency because it delivers the right dose with just a click of a button. Other kits contain a prefilled epinephrine syringe. The IM route is recommended over the subcutaneous route because it has more predictable and rapid absorption. The dose should be repeated in 15 minutes if signs and symptoms persist (see [Chapter 22](#) for further discussion of epinephrine administration for anaphylaxis management).

After epinephrine administration, an antihistamine such as diphenhydramine (Benadryl, Allerdryl ) or chlorpheniramine (Chlor-Trimeton, Novo-Pheniramin ) is also given. In the field setting, oral liquid diphenhydramine (available over the counter) may be easier for the victim to swallow than the tablet form if there is tongue or pharyngeal edema. *Call 911 to transport the patient to a medical facility as soon as possible.*

Hospital Care

Once in a clinical setting, patients who sustain serious reactions to bee or wasp stings need oxygen administration and continuous cardiac and blood pressure monitoring. Establish an IV infusion with normal saline solution to support blood pressure. Advanced life support drugs and equipment should be made immediately available. If epinephrine IM fails to relieve the life-threatening reaction, a stronger solution may be requested as a very slow IV bolus.

NURSING SAFETY PRIORITY

Drug Alert

IV epinephrine administration has much greater risk for adverse cardiovascular effects than IM epinephrine. Use the IV form of epinephrine with extreme caution, especially in older adults with cardiovascular disease, because it can increase pulse rate and blood pressure. Monitor the patient's vital signs every 10 to 15 minutes for 1 hour after IV administration.

Bronchospasm can be treated with albuterol (Proventil, Novo-Salmol ) via inhalation or a similar bronchodilating agent. Parenteral antihistamines, such as diphenhydramine (Benadryl, Allerdryl ) and corticosteroids are also commonly prescribed to decrease the immune response. The toxin in the bee and wasp venom may outlast the effects of the initial doses of epinephrine and antihistamines and cause a recurrence of the allergic reaction over time. Therefore doses may need to be repeated for hours or days. Corticosteroids in tapered doses are often given to manage or prevent delayed allergic effects, termed a *biphasic reaction*, which generally occurs within 4 to 6 hours of the sting; however, the

evidence regarding the effectiveness of corticosteroid administration is unclear (Choo et al., 2010).

All patients who have sustained multiple stings (particularly more than 50) are observed in an emergency care setting for several hours to monitor for the development of toxic venom effects. A critical care admission may be needed.

NURSING SAFETY PRIORITY

Action Alert

Teach anyone who develops an allergic reaction to bee or wasp stings to always carry a prescription epinephrine emergency kit and wear a medical alert tag or bracelet.

DECISION-MAKING CHALLENGE

Evidence-Based Practice

A patient who is on vacation is admitted to a local rural emergency department after being stung 10 minutes ago by a small honeybee. The patient's husband states that she is allergic to bees and forgot her bee kit. As her nurse, you assess mild respiratory distress, upper arm swelling at the sting site, and increasing anxiety. Her lung assessment reveals wheezing on inspiration, her respiratory rate is 32, and her blood pressure is 158/70 mm Hg. She has no history of hypertension.

1. For what complications will you monitor and why?
2. The physician will likely prescribe epinephrine for this patient. What assessments will you perform after giving this medication and why?
3. What other drugs will likely be prescribed for this patient and why?
4. What is likely causing her elevated blood pressure at this time?

LIGHTNING INJURIES

Pathophysiology

Lightning is a year-round force of nature responsible for multiple injuries and deaths each year. It is caused by an electric charge generated within thunderclouds that may become cloud-to-ground lightning—the most dangerous form to people and structures. Young adult males account for the majority of lightning-related deaths. Most lightning-related injuries occur in the summer months during the afternoon and early evening because of increased thunderstorm activity and greater numbers of people spending time outside. Anyone without adequate shelter, including golfers, hikers, campers, beach-goers, and swimmers, is at risk.

Lightning has an enormous magnitude of energy and a different current flow than a typical high-voltage electric shock. The duration of contact is nearly instantaneous, resulting in a flashover phenomenon—an effect that may account for the relatively low overall mortality rate. Because water is a conductor of electricity and current takes the path of least resistance to the ground, any wetness on the body increases the flashover effect of a lightning strike. Lightning flashover produces an explosive force that can injure victims directly, as well as cause them to fall or to be thrown. The clothing and shoes of victims may be damaged or blown off in the process.

Lightning produces injury by directly striking a victim, by splashing off a nearby object, or by traveling through the

ground. Although few people die after a lightning strike, many survivors are left with permanent disabilities.

Health Promotion and Maintenance

Injuries caused by lightning strike are highly preventable. Teach people to stay indoors during an electrical storm. [Chart 11-6](#) lists common prevention strategies.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Both the cardiopulmonary and the central nervous systems are profoundly affected by lightning injuries. *The most lethal initial effect of massive electrical current discharge on the cardiopulmonary system is cardiac arrest.* Because cardiac cells are autorhythmic, an effective cardiac rhythm may return spontaneously. However, prolonged respiratory arrest from impairment of the medullary respiratory center can produce hypoxia and, subsequently, a second cardiac arrest. Therefore, when attempting to manage multiple victims of a lightning strike, provide care to those who are in cardiopulmonary

arrest first. Initiate resuscitation measures with immediate airway and ventilatory management, chest compressions, and other appropriate life-support interventions.

People who survive the immediate lightning strike may be treated in a less emergent fashion. However, these victims can have serious myocardial injury, which may be manifested by ECG and myocardial perfusion abnormalities, such as angina and dysrhythmias. The initial appearance of mottled skin and decreased to absent peripheral pulses usually arises from arterial vasospasm and typically resolves spontaneously in several hours.

Central nervous system (CNS) injury is common in lightning strike victims. A classic finding is an immediate but temporary paralysis that affects the lower limbs to a greater extent than the upper limbs. This condition usually resolves within hours. Other clinical manifestations and complications resulting from lightning strikes are listed in [Chart 11-6](#). Lightning strikes also cause skin burns. Most burns are superficial and heal without incident. Patients may have full-thickness burns, charring, and contact burns from overlying metal objects. An uncommon but characteristic skin manifestation of lightning is the appearance of branching or ferning marks on the skin called [Lichtenberg figures](#).

INTERVENTIONS

First Aid/Prehospital Care

Because of lightning's powerful impact to the body, patients are at great risk for multi-system trauma. The full extent of injury may not be known until thorough monitoring and diagnostic evaluation can be performed in the hospital. Initial care includes spinal immobilization with priority attention to stabilization of airway, breathing, and circulation through standard basic and advanced life support measures. Cardiopulmonary resuscitation (CPR) is performed immediately when a person is in cardiac arrest. If cardiopulmonary or CNS injury is present, skin burns are *not* an initial priority. However, if time and resources permit, a sterile dressing may be applied to cover the sites. *Victims of lightning strike are not electrically charged; the rescuer is in no danger from physical contact.* Nonetheless, the storm can present a continued threat to everyone in the vicinity who lacks adequate shelter. Contrary to popular belief, lightning can and does strike in the same place more than once.

Hospital Care

Once in the acute care hospital setting, the focus of care is advanced life support management, including cardiac monitoring to detect cardiac dysrhythmias and a 12-lead ECG. The patient may require mechanical ventilation until spontaneous breathing returns. Collaborate with the health care team to perform a thorough physical and diagnostic evaluation to identify obvious and occult (hidden) traumatic injuries because the patient may have suffered a fall or blast effect during the strike. A creatine kinase (CK) measurement may be requested to detect skeletal muscle damage resulting from the lightning strike. In severe cases, rhabdomyolysis (circulation of by-products of skeletal muscle destruction) can lead to renal failure. Burn wounds are assessed and treated according to standard burn care protocols. Tetanus prophylaxis is necessary for burns or any break in skin integrity. Some institutions

CHART 11-6 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Lightning Strike Prevention

- Observe weather forecasts when planning to be outside.
- Seek shelter when you hear thunder. Safe areas include the nearest building or an enclosed vehicle. Isolated sheds and the entrances to caves are dangerous, however. Do not stand under an isolated tall tree or structure (e.g., ski lift, flagpole, boat mast, power line) in an open area such as a field, ridge, or hilltop; lightning seeks the highest point. A stand of dense trees offers better protection.
- Leave the water immediately (including an indoor shower or bathtub), and move away from any open bodies of water.
- Avoid metal objects like chairs or bleachers; put down tools, fishing rods, garden equipment, golf clubs, and umbrellas; stand clear of fences, exposed pipes, motorcycles, bicycles, tractors, and golf carts.
- If camping in a tent, stay away from the metal tent poles and wet walls.
- Once inside a building, stay away from open doors, windows, fireplaces, metal fixtures, and plumbing.
- Turn off electrical equipment including computers, televisions, and stereos.
- Stay off the telephone. Lightning can enter through the telephone line and produce head and neck trauma, including cataracts and tympanic membrane disruption. Death can result.
- If you are caught out in the open and cannot seek shelter, attempt to move to lower ground such as a ravine or valley; stay away from any tall trees or objects that could result in a lightning strike splashing over to you; place insulating material between you and the ground (e.g., sleeping pad, rain parka, life jacket). A lightning strike is imminent if your hair stands on end, you see blue halos around objects, and hear high-pitched or crackling noises. If you cannot move away from the area immediately, crouch on the balls of your feet and tuck your head down to minimize the target size; do not lie down on the ground or have hand contact with the ground.

transfer these victims to a burn center for follow-up management.

COLD-RELATED INJURIES

Two common cold-related injuries are hypothermia and frostbite. Both types of injuries can be prevented by implementing protection from the cold. Teach patients at risk ways to prevent these injuries, which can range from mild discomfort to major systemic complications.

HEALTH PROMOTION AND MAINTENANCE

When participating in cold weather activities, clothing choices are critical to the prevention of hypothermia and frostbite. Teach the importance of wearing synthetic clothing because it moves moisture away from the body and dries fast. Cotton clothing, especially as an undergarment, holds moisture, becomes wet, and contributes to the development of hypothermia. Cotton clothing should be strictly avoided in a cold outdoor environment; this rule applies to gloves and socks as well. Wet socks and gloves promote frostbite in the toes and fingers. Wearing too many pairs of socks can decrease circulation and lead to frostbite.

Clothing should be layered so that it can be easily added or removed as the temperature changes. The inner layers, such as polyester fleece, provide warmth and insulation. The outer layer's purpose is to block the wind and provide moisture protection. This layer is best made of a windproof, waterproof, breathable fabric such as GORE-TEX. A hat is an essential clothing item that significantly decreases body heat loss through the head. Face protection with a facemask should be used on particularly cold days when wind chill poses a risk. Sunscreen (SPF 30) and sunglasses are also important to protect skin and eyes from the sun's harmful rays.

When driving in winter cannot be avoided, teach people to keep water, extra clothing, and food in their car in case the vehicle becomes stranded. Maintaining personal fitness and conditioning are also important considerations to prevent hypothermia and frostbite. People should not diet or restrict food or fluid intake when participating in winter outdoor activities. Malnutrition and dehydration contribute to cold-related illnesses and injuries. Finally, it is important for people to know their physical limits and to come in out of the cold when these limits have been reached.

HYPOTHERMIA

Pathophysiology

Hypothermia is a core body temperature below 95° F (35° C). Common predisposing conditions that promote hypothermia include:

- Cold water immersion
- Acute illness (e.g., "flu")
- Traumatic injury
- Shock states
- Immobilization
- Cold weather (especially for the homeless and people working outdoors)

- Advanced age
- Selected medications (e.g., phenothiazines, barbiturates)
- Alcohol intoxication
- Malnutrition
- Hypothyroidism
- Inadequate clothing or shelter (e.g., the homeless population)

An environmental temperature below 82° F (28° C) can produce hypothermia in any susceptible person. *Therefore people, especially older adults, are actually at risk on a year-round basis in most areas of the world.* Wind chill is a significant factor: heat loss increases as wind speed rises. Wet conditions further increase heat loss through evaporation. Weather is the most common cause of hypothermia for outdoor sports enthusiasts and for those with inadequate clothing or shelter. It is also a problem for the older adult, the homeless, and the poor who cannot afford heating.

NCLEX EXAMINATION CHALLENGE

Health Promotion and Maintenance

An older client is preparing for a trip to a cold-weather area and asks the nurse how he can prevent hypothermia while visiting there. Which preventive actions will the nurse include in the health teaching? **Select all that apply.**

- A. Wear cotton clothing to help absorb moisture.
- B. Layer clothing to keep heat near the body.
- C. Avoid skiing if it is snowing heavily.
- D. Be sure to wear gloves and a hat.
- E. Do not wear too many pairs of socks.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Hypothermia is commonly divided into three categories by severity: *mild* (90° to 97° F [32° to 36° C]); *moderate* (82° to 90° F [28° to 32° C]); and *severe* (below 82° F [28° C]). Treatment decisions are based on the severity of hypothermia. **Chart 11-7** summarizes by category the common key features for the patient who is hypothermic.

INTERVENTIONS

First Aid/Prehospital Care

For treatment of *mild hypothermia*, the person needs to be sheltered from the cold environment, have all wet clothing removed, and undergo passive or active external rewarming. Passive methods involve applying warm clothing or blankets. Active methods incorporate heating blankets, warm packs, and convective air heaters or warmers to speed rewarming. If a heating blanket is used, monitor the patient's skin at least every 15 to 30 minutes to reduce the risk for burn injury.

In the case of mild, uncomplicated hypothermia as the only health problem, having the victim drink warm high-carbohydrate liquids that do not contain alcohol or caffeine can aid in rewarming. Alcohol is a peripheral vasodilator; both alcohol and caffeine are diuretics. These effects can potentially worsen dehydration and hypothermia.

CHART 11-7 KEY FEATURES

Hypothermia**Mild**

- Shivering
- Dysarthria (slurred speech)
- Decreased muscle coordination
- Impaired cognition (“mental slowness”)
- Diuresis (caused by shunting of blood to major organs)

Moderate

- Muscle weakness
- Increased loss of coordination
- Acute confusion
- Apathy
- Incoherence
- Possible stupor
- Decreased clotting (caused by impaired platelet aggregation and thrombocytopenia)

Severe

- Bradycardia
- Severe hypotension
- Decreased respiratory rate
- Cardiac dysrhythmias, including possible ventricular fibrillation or asystole
- Decreased neurologic reflexes
- Decreased pain responsiveness
- Acid-base imbalance

Hospital Care

General management principles apply to both *moderate* and *severe* hypothermia. Protect patients from further heat loss and handle them gently to prevent ventricular fibrillation. Positioning the patient in the supine position prevents orthostatic changes in blood pressure from cardiovascular instability. Follow standard resuscitation efforts with special attention to maintenance of airway, breathing, and circulation as recommended by the American Heart Association (2005b):

- Administer drugs with caution and/or spaced at longer intervals because metabolism is unpredictable in hypothermic conditions.
- Remember that drugs can accumulate without obvious therapeutic effect while the patient is cold but may become active and potentially lead to drug toxicity as effective rewarming is underway.
- Consider withholding IV drugs until the core temperature is above 86° F (30° C).
- Initiate CPR for patients without spontaneous circulation.
- Be aware that defibrillation attempts may be ineffective until the core temperature is above 86° F (30° C).

Treatment of *moderate* hypothermia may involve active external and core rewarming methods. Applying external heat with heating blankets can promote core temperature “after-drop” by producing peripheral vasodilation. “**After-drop**” is the continued decrease in core body temperature after the victim is removed from the cold environment; it is caused by the return of cold blood from the periphery to the central circulation. Therefore the patient’s trunk should be actively rewarmed before the extremities. Core rewarming methods

for moderate hypothermia include administration of warm IV fluids, heated oxygen or inspired gas to prevent further heat loss via the respiratory tract, and heated peritoneal, pleural, gastric, or bladder lavage.

! NURSING SAFETY PRIORITY**Critical Rescue**

Patients who are *severely* hypothermic are at high risk for cardiac arrest. Avoid using active *external* rewarming with heating devices because it is dangerous and contraindicated in this population due to rapid vasodilation.

The treatment of choice for *severe* hypothermia is to use *internal* rewarming methods such as cardiopulmonary bypass, hemodialysis, venovenous or arteriovenous rewarming, or intravascular rewarming via a closed-loop indwelling catheter (Lasater, 2008). Cardiopulmonary bypass is the fastest core rewarming technique. However, this device is not available in all hospitals. It also requires specialized personnel and resources to operate it properly. Monitor for early signs of complications that can occur after rewarming, such as fluid, electrolyte, and metabolic abnormalities; acute respiratory distress syndrome (ARDS); acute renal failure; and pneumonia.

A long-standing principle in the treatment of patients with hypothermic cardiac arrest is that “no one is dead until they are warm and dead.” There is a factual basis to this statement when considering the number of survivors who have suffered a prolonged hypothermic cardiac arrest. Prolonged resuscitation efforts may not be reasonable in cases in which survival appears highly unlikely, such as in an anoxic event followed by a hypothermic cardiac arrest.

FROSTBITE**Pathophysiology**

Another significant cold-related injury that may or may not be associated with hypothermia is frostbite. The main risk factor is inadequate insulation against cold weather; that is, either the skin is exposed to the cold or the person’s clothing offers insufficient protection. Wet clothing, in particular, is a poor insulator and facilitates the development of frostbite. Fatigue, dehydration, and poor nutrition are other contributing factors. People who smoke, consume alcohol, or have impaired peripheral circulation have a higher incidence of frostbite. Any previous history of frostbite further increases a person’s susceptibility.

PATIENT-CENTERED COLLABORATIVE CARE**ASSESSMENT**

Frostbite occurs when body tissue freezes and causes damage. Like burns, frostbite injuries can be superficial, partial, or full thickness. By contrast, **frostnip** is a type of superficial cold injury that may produce pain, numbness, and pallor of the affected area but is easily relieved by applying warmth; it does not cause tissue damage. Frostnip typically develops on skin areas such as the face, nose, finger, or

FIG. 11-7 Edema and blister formation 24 hours after frostbite injury occurring in an area covered by a tightly fitted boot.

toes. Untreated, it is a precursor to more severe forms of frostbite.

First-degree frostbite, the least severe type of frostbite, involves **hyperemia** (increased blood flow) of the involved area and edema formation. In *second-degree frostbite*, large fluid-filled blisters develop with partial-thickness skin necrosis (Fig. 11-7). *Third-degree frostbite* appears as small blisters that contain dark fluid and an affected body part that is cool, numb, blue, or red and does not blanch. Full-thickness and subcutaneous tissue necrosis occur and require débridement. In *fourth-degree frostbite*, the most severe form, there are no blisters or edema; the part is numb, cold, and bloodless. The full-thickness necrosis extends into the muscle and bone. At this stage, gangrene develops, which may require amputation of the affected part.

INTERVENTIONS

First Aid/Prehospital Care

Recognition of frostbite is essential to early, effective intervention and prevention of further tissue damage. Asking a partner to frequently observe for early signs of frostbite such as a white, waxy appearance to exposed skin, especially on the nose, cheeks, and ears, is an effective strategy to identify the problem before it worsens. In this case, the best remedy is to have the person seek shelter from the wind and cold and to attend to the affected body part (Laskowski-Jones, 2009). Superficial frostbite is easily managed using body heat to warm the affected area. Teach patients to place their warm hands over the affected areas on their face or to place cold hands under the arms.

Hospital Care

Patients with more severe and deeper forms of frostbite need aggressive management. For all degrees of partial-thickness to full-thickness frostbite, rapid rewarming in a water bath at a temperature range of 104° to 108° F (40° to 42° C) is indicated to thaw the frozen part (Auerbach et al., 2008). If a warming tub is not available, use hot towels instead. Because patients experience severe pain during the rewarming process, this intervention is best accomplished in a medical facility; however, it may be done in another setting if no other options exist for prompt transport or rescue. Administer analgesics, especially IV opiates, and IV rehydration.

! NURSING SAFETY PRIORITY

Critical Rescue

Do not apply dry heat or massage the frostbitten areas as part of the warming process. These actions can produce further tissue injury.

When the rewarming process is complete, handle the injured areas gently and elevate them above heart level if possible to decrease tissue edema. Sometimes splints are used to immobilize extremities during the healing process. Assess the person at least hourly for the development of compartment syndrome—a limb-threatening complication caused by severe neurovascular impairment. Observe for early manifestations, which include increasing pain (even after analgesics are given) and paresthesias (painful tingling and numbness). Compare the affected extremity with the unaffected one to assess for pallor. Assess for pulses and muscle weakness. Management of compartment syndrome is discussed in detail in Chapter 54.

Frostbite destroys tissue and produces a deep tetanus-prone wound; the patient should be immunized to prevent tetanus. Apply only loose, nonadherent sterile dressings to the damaged areas. Avoid compression of the injured tissues. Both topical and systemic antibiotics may be used. Once a patient's frozen part has thawed, do not allow it to refreeze, which worsens the injury. Antiprostaglandin therapy with ibuprofen may be used because it may decrease tissue damage for some patients (Auerbach et al., 2008).

In cases of severe, deep frostbite, débridement of necrotic tissue may be needed to evaluate tissue viability and provide wound management. Amputation may be indicated for patients with severe injuries or for those who develop gangrene or severe compartment syndrome.

DECISION-MAKING CHALLENGE

Patient-Centered Care

A patient is admitted with severe frostbite of both feet and toes as a result of getting lost while hiking in a mountainous area. He cannot feel the frostbitten areas, and the skin over his feet is red and blue. The affected skin does not blanch, and both feet are very swollen. He states that he is worried that he will “lose his feet.”

1. How will you respond to the patient's concern at this time?
2. The patient undergoes a warming process to thaw his feet. What response will the patient likely experience, and how will you be prepared to intervene?
3. After receiving morphine for increasing pain, the patient reports severe pain and burning in his feet. What is your best action at this time?
4. For what complications is this patient at risk and why?

ALTITUDE-RELATED ILLNESSES

Pathophysiology

High altitude illnesses, also known as **high altitude disease (HAD)** or *altitude sickness*, cause pathophysiologic responses in the body as a result of exposure to low partial pressure of oxygen at high elevations. Although most consider high altitude to be an elevation over 5000 feet, millions of people worldwide who ascend to or live at altitudes above 2500 feet are at risk for acute and chronic mountain sickness.

As altitude increases, atmospheric (barometric) pressure decreases. Oxygen makes up 21% of the pressure. Therefore, as this pressure falls, the partial pressure of oxygen in the air decreases, resulting in less available oxygen to humans. The pathophysiologic consequence is hypoxia. Hypoxia is more pronounced as elevation increases.

Elevations higher than 18,000 feet are extreme altitudes. Supplemental oxygen is necessary at these levels to prevent altitude-related illnesses, including death, from occurring during abrupt ascent.

The cause of HAD is an interaction of environmental and genetic factors (Guoen et al., 2009). Those who are obese or have chronic illnesses, especially cardiovascular problems, are more at risk than those who are thinner and healthier. Dehydration and central nervous system depressants, such as alcohol, also increase the risk. The age of the person does not seem to be a factor in altitude-related illnesses.

GENETIC/GENOMIC CONSIDERATIONS

Genetic differences among certain ethnic groups who live in high altitude areas have been studied. For example, chronic mountain sickness is less common in Tibetans and Sherpas than in Andeans, Hans, or Peruvian Quechuas (Guoen et al., 2009).

In addition, the pathogenesis of mountain sickness is associated with unidentified mutant forms of hypoxia-related genes, the human leukocyte antigen (HLA) system, and certain genes that encode protein. Examples of genes that may mutate and contribute to the development of HAD include:

- *EPO* (erythropoietin), which regulates red blood cell production
- *HIF1A* (hypoxia inducible factor), which mediates the effects of hypoxia on body cells
- *EDN1* (endothelin), which causes vasoconstriction and thus increases blood pressure
- *NOS3* (endothelial nitric oxide synthase), which makes nitric acid in vascular tissue to maintain vessel tone and altitude adaptation

At this time, no clinical genetic testing to determine a person's risk of altitude sickness is available; however, further research is being conducted to identify specific gene mutations that contribute to altitude-related illnesses.

The process of adapting to high altitude is called *acclimatization*. **Acclimatization** involves physiologic changes that help the body adapt to less available oxygen in the atmosphere. As the carotid bodies sense a decline in P_{aO_2} at about 5000 feet, they increase the respiratory rate to improve oxygen delivery. This mechanism is called the “hypoxic-ventilatory response.” Increased respiratory rate causes **hypocapnia** (decreased carbon dioxide) and respiratory alkalosis, which limit further increases in respiratory rate. Rapid eye movement (REM) sleep is impaired. Hypoxia can occur from periods of apnea. Within 24 to 48 hours of being at high altitude, the kidneys excrete the excess bicarbonate, which helps the pH to return to normal and ventilatory rate to again increase.

Increased sympathetic nervous system activity increases heart rate, blood pressure, and cardiac output. Pulmonary artery pressure rises as an effect of generalized hypoxia-induced pulmonary vasoconstriction. Cerebral blood flow increases to maintain cerebral oxygen delivery. Hypoxia also induces red blood cell production by stimulating the release of erythropoietin. The result is an increase in red blood cells and hemoglobin concentration. Over time, polycythemia can develop in people who remain in a high altitude environment.

People who plan to climb to high altitudes are advised to ascend slowly, over the course of days or even weeks, depending on the degree of elevation. Ascending too rapidly is the primary cause of altitude-related illnesses. They are much

more common in people who sleep at elevations above 8000 feet.

The three most common clinical conditions that are considered high altitude illnesses are acute mountain sickness (AMS), high altitude cerebral edema (HACE), and high altitude pulmonary edema (HAPE). AMS may occur with HACE and/or HAPE; the underlying pathophysiology is hypoxia. Chronic mountain sickness can occur in people who live at high elevations. Although each syndrome has several unique manifestations, the basic assessment and management approach are the same.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Assessment findings for the typical patient with AMS include reports of throbbing headache, anorexia, nausea, and vomiting. Feeling chilled, irritable, and apathetic are also associated with AMS. The syndrome produces effects similar to an alcohol-induced hangover. The patient may relate a feeling of extreme illness. Vital signs are variable: the patient can be tachycardic or bradycardic, have normal blood pressure, or have postural hypotension. He or she may experience dyspnea both on exertion and at rest. Exertional dyspnea is expected as a person adjusts to high altitude. However, dyspnea at rest is abnormal and may signal the onset of HAPE.

If AMS progresses to *high altitude cerebral edema (HACE)*, the extreme form of this disorder, the patient cannot perform ADLs and has extreme apathy. A key sign of HACE is the development of ataxia (defective muscular coordination). The patient also has a change in mental status with confusion and impaired judgment. Cranial nerve dysfunction and seizures may occur. If untreated, a further decline in the patient's level of consciousness results. Stupor, coma, and death can result from brain swelling and the subsequent damage caused by increased intracranial pressure over the course of 1 to 3 days.

High altitude pulmonary edema (HAPE) often appears in conjunction with HACE but may occur during the progression of AMS within the first 2 to 4 days of a rapid ascent to high altitude, commonly on the second night. It is the most common cause of death associated with high altitude. Patients notice poor exercise tolerance and a prolonged recovery time after exertion. Fatigue and weakness, as well as other signs and symptoms of AMS, are present. Important clinical indicators of HAPE include a persistent dry cough and cyanosis of the lips and nail beds. Tachycardia and tachypnea occur at rest. Crackles may be auscultated in one or both lungs. Pink, frothy sputum is a late sign of HAPE. A chest x-ray demonstrates pulmonary infiltrates and pulmonary edema. Arterial blood gas analysis shows respiratory alkalosis and hypoxemia (decreased oxygen). Pneumonia also may be present. Pulmonary artery pressure is usually very elevated due to pulmonary edema.

INTERVENTIONS

First Aid/Prehospital Care

The most important intervention to manage serious altitude-related illnesses is descent to a lower altitude. Patients must be monitored carefully for any evidence of symptom

progression. With mild AMS, the victim should be allowed to rest and acclimate at the current altitude. The person is instructed not to ascend to a higher altitude, especially for sleep, until symptoms lessen. If symptoms persist or worsen, he or she should be moved to a lower altitude as soon as possible. Even a descent of about 1600 feet may improve the patient's condition and reverse altitude-related pathologic effects. Oxygen should also be administered if available to effectively treat symptoms of AMS.

Prevention and Treatment

The oral drug *acetazolamide* (Diamox, Apo-Acetazolamide) is commonly used to both prevent and treat AMS (Luks & Swenson, 2008). Acetazolamide is a carbonic anhydrase inhibitor. It acts by causing a bicarbonate diuresis, which rids the body of excess fluid, and induces metabolic acidosis. The acidotic state increases respiratory rate and decreases the occurrence of periodic respiration during sleep at night. In this way, it helps patients acclimate faster to a high altitude. For best results, the drug should be taken 24 hours before ascent and be continued for the first 2 days of the trip.

! NURSING SAFETY PRIORITY

Drug Alert

Because acetazolamide is a sulfa drug, ask about an allergy to sulfa before the patient takes the drug because it may cause hypersensitivity reactions in those who are sulfa-sensitive.

Another drug that is indicated in the treatment of moderate to severe AMS is dexamethasone (Decadron, Deronil). This drug's mechanism of action is unclear for AMS treatment, but it reduces cerebral edema by dehydrating the central nervous system. It does not speed acclimatization like acetazolamide does, but it does relieve the symptoms of AMS. Symptoms may recur when the drug is stopped.

For the treatment of HACE, early recognition of ataxia or a change in level of consciousness should prompt a rapid descent by rescuers or companions to a lower altitude. While undergoing descent, the patient can be given supplemental oxygen and dexamethasone. If mental status is severely impaired and the patient's airway is at risk, all drugs should be given parenterally. Ultimately, the patient with HACE must be admitted to the hospital. Critical care management may be necessary.

Like HACE, early recognition of HAPE is essential to improve the patient's chance for survival. Phosphodiesterase inhibitors such as tadalafil (Cialis) and sildenafil (Viagra) may be used to prevent HAPE due to their pulmonary vasodilatory effects (Luks & Swenson, 2008). When it occurs, HAPE is a serious condition that requires quick evacuation to a lower altitude, oxygen administration, and bedrest to save the patient's life. If descent must be delayed because of weather conditions or other factors, oxygen administration is essential as soon as possible. Keep the patient warm at all times. Drugs are not substitutes for descent and oxygen. However, the treatment of HAPE may include the calcium channel blocker nifedipine (Procardia, Adalat PA) to decrease pulmonary vascular resistance (Luks & Swenson, 2008). Hospital admission is required. In uncomplicated cases of HAPE, recovery occurs quickly but effects such as weakness and fatigue may persist for 2 weeks.

CHART 11-8 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Preventing, Recognizing, and Treating Altitude-Related Illnesses

- Plan a slow ascent to allow for acclimatization.
- Learn to recognize clinical manifestations of altitude-related illnesses.
- Avoid overexertion and overexposure to cold; rest at present altitude.
- Ensure adequate hydration and nutrition.
- Avoid alcohol and sleeping pills when at high altitude.
- For progressive or advanced acute mountain sickness (AMS), recognize symptoms and implement an immediate descent; provide oxygen at high concentration.
- To prevent the occurrence of AMS, discuss the use of acetazolamide (Diamox) and other agents as indicated with your health care provider.
- Protect skin and eyes from the sun's harmful ultraviolet rays at high altitude. Wear sunscreen (at least SPF 30) and high-quality wraparound sunglasses or goggles.

Chart 11-8 summarizes best practices for preventing, recognizing, and treating altitude-related illnesses.

? NCLEX EXAMINATION CHALLENGE

Physiological Integrity

A client experiences altitude-related illness after visiting a ski resort in Colorado. What is the nurse's priority action when the client is admitted to the emergency department?

- Provide supplemental oxygen.
- Place the client on a ventilator.
- Perform an electrocardiogram.
- Insert a nasogastric tube.

DROWNING

Pathophysiology

Drowning is a leading cause of accidental death in the United States. It occurs when a person suffers primary respiratory impairment from submersion or immersion in a liquid medium (usually water) (Layon & Modell, 2009). **Near-drowning** was previously defined as recovery after submersion; however, this term is no longer used because language that describes drowning incidents has been standardized (American Heart Association, 2005a). Today the drowning process is considered a continuum with outcomes that range from survival to death. Approximately 1 of every 13 drowning victims dies in the United States (Layon & Modell, 2009).

Health Promotion and Maintenance

Prevention is the key to avoiding drowning incidents. When providing health teaching, include these points:

- Constantly observe people who cannot swim and are in or around water.
- Do not swim alone.
- Test the water depth before diving in head first; never dive into shallow water.

- Avoid alcoholic beverages when swimming and boating and while in proximity to water.
- Ensure that water rescue equipment, such as life jackets, flotation devices, and rope, is immediately available when around water.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

When water is aspirated into the lungs, the makeup of the water is a factor in the pathophysiology of the drowning event. Aspiration of fresh water causes surfactant to wash out of the lungs. Surfactant reduces surface tension within the alveoli, increases lung compliance and alveolar radius, and decreases the work of breathing. Loss of surfactant from fresh water aspiration destabilizes the alveoli and leads to increased airway resistance. Conversely, salt water—a hypertonic fluid—creates an osmotic gradient that draws protein-rich fluid from the vascular space into the alveoli. Pulmonary edema results. Another concern is water quality during the submersion event. The victim's outcome may be negatively affected by contaminants in the water such as chemicals, algae, microbes, sand, and mud. These substances can worsen lung injury and cause a lung infection.

The duration and severity of hypoxia are the two most important factors that determine outcomes for victims of drowning. Very cold water seems to have a protective effect. Successful resuscitations have been reported even after prolonged arrest intervals. Hypothermia might offer some protection to the hypoxic brain by reducing cerebral metabolic rate. The diving reflex is a physiologic response to asphyxia, which produces bradycardia, a reduction in cardiac output, and vasoconstriction of vessels in the intestine, skeletal muscles, and kidneys. These physiologic effects are thought to reduce myocardial oxygen use and enhance blood flow to the heart and cerebral tissues. Survival may be linked to some combination of the effects of hypothermia and the diving reflex.

The cause of the submersion should also be determined, if possible. The patient may have suffered a medical condition or injury that caused the drowning event such as a seizure, myocardial infarction, stroke, or spinal cord injury while in the water. Injuries sustained from diving into shallow water or body surfing, such as cervical spine trauma, can also increase the difficulty of rescue and resuscitation efforts.

INTERVENTIONS

First Aid/Emergency Care

Immediate emergency care focuses on a safe rescue of the victim. Potential rescuers must consider their own swimming abilities and limitations, as well as any natural or human-made hazards, before attempting to save the victim; failure to do so could place additional lives in jeopardy. *Once rescuers gain access to the victim, the priority is safe removal from the water.* Spine stabilization with a board or floatation device should be considered only for those victims who are at high risk for spine trauma (e.g., history of diving, use of a water slide, signs of injury or alcohol intoxication), as opposed to all drowning victims (American Heart Association, 2005a). Time is of the essence; efforts directed toward a rapid rescue have the most potential benefit. Initiate airway clearance and ventilatory support measures as soon as possible—usually once the person is in shallow water or out of the water altogether, because effective airway and ventilation measures are very difficult to perform in deep water. If hypothermia is a concern, handle the victim gently to prevent ventricular fibrillation.

! NURSING SAFETY PRIORITY

Critical Rescue

Do not attempt to get the water out of the victim's lungs; deliver abdominal or chest thrusts only if airway obstruction is suspected.

Hospital Care

Once the person is safely removed from the water, airway and cardiopulmonary support interventions begin, including oxygen administration, endotracheal intubation, CPR, and defibrillation, if necessary. In the clinical setting, gastric decompression with a nasogastric or orogastric tube is needed to prevent aspiration of gastric contents and improve ventilatory function. After a period of artificial ventilation by mask, the victim typically has a distended abdomen, which impairs movement of the diaphragm and decreases lung ventilation. Patients who experience drowning require complex care to support their major body systems. The full spectrum of critical care technology may be needed to manage the pathophysiologic complications of drowning, including pulmonary infection, acute respiratory distress syndrome (ARDS), and CNS impairment. These complications are discussed elsewhere in this text.

GET READY FOR THE NCLEX® EXAMINATION!

KEY POINTS

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Assess high-risk patients, especially older adults, for their knowledge of safety precautions to prevent heat-related and cold-related injuries.

- Assess high-risk patients, including those who do not know how to swim, for their knowledge of safety precautions to avoid drowning events.

Health Promotion and Maintenance

- Teach people how to prevent heat-related illnesses as outlined in [Chart 11-1](#).

GET READY FOR THE NCLEX® EXAMINATION! —cont'd

- Teach people how to prepare for cold environments, including proper clothing (no cotton) and avoidance of wind and wet weather.
- Teach people how to prevent arthropod bites and stings as described in [Chart 11-5](#).
- Teach people how to avoid getting bitten by a snake as listed in [Chart 11-4](#).

Physiological Integrity

- Heat-related injuries can be mild (heat exhaustion) to severe (heat stroke).
- The priority for first aid for heat stroke, after a patent airway is established, is to cool the patient as quickly as possible (see [Chart 11-3](#)).
- North American pit vipers can be identified by the triangular-shaped head and retractable fangs; nonpoisonous snakes do not have these features.
- The management of a patient who has a snakebite depends on the severity of envenomation (venom injection) (see [Table 11-1](#)); both local and systemic manifestations can occur.
- The priority for first aid when a patient has a snakebite is to decrease the venom circulation.
- Antivenom drugs are available for most types of poisonous snakebites; monitor for an allergic response when these medications are given.
- The bite of a brown recluse spider can cause tissue necrosis; in rare cases, systemic manifestations can occur, including death.
- Cold applications, such as ice, should be used as first aid for poisonous spider bites.
- The venom of a bark scorpion is neurotoxic; monitor the patient for signs of respiratory failure that may require mechanical ventilation.
- Single bee and wasp stings cause local reactions unless the person is allergic to them.
- Epinephrine is the drug of choice for bee and wasp sting allergic reactions, followed by an antihistamine drug.
- The best way to prevent lightning injuries is to avoid places where lightning is likely to strike ([Chart 11-6](#)).
- Lightning causes central nervous system and cardiovascular complications, as well as skin burns.
- Two common cold injuries are hypothermia and frostbite; both may be prevented by selecting appropriate layered clothing; cotton should not be worn.
- In moderate to severe cases of hypothermia, coagulopathy (abnormal clotting) or cardiac failure can occur.
- The priority for care of a patient with a cold injury is warming; alcohol should be avoided.
- Frostbite can be mild (frostnip) to serious (fourth degree); severe frostbite can result in amputation due to compartment syndrome or gangrene.
- High altitude can cause a range of physiologic consequences in the body, primarily due to hypoxia.
- The priority for care of the patient with illness related to high altitude is descent to a lower altitude.
- Acetazolamide (Diamox, Apo-Acetazolamide 🍁) is the drug of choice for prevention and treatment of mild altitude-related illness.
- [Chart 11-8](#) outlines best practice strategies for preventing, recognizing, and treating altitude-related illnesses.
- Drowning victims often require cardiopulmonary support, including CPR.
- The patient who has been submersed in water is at risk for pulmonary infection, ARDS, and central nervous system impairment.

Concepts of Emergency and Disaster Preparedness

Linda Laskowski-Jones

<http://evolve.elsevier.com/Iggy/>

Answer Key for NCLEX Examination Challenges and
Decision-Making Challenges
Audio Glossary

Key Points
Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Apply principles of triage to prioritize care delivery in a disaster situation.
2. Identify the roles of the nurse in emergency preparedness and response.
3. Compare the key personnel roles in an emergency preparedness and response plan.
4. Describe the components of an emergency preparedness and response plan.

5. Develop a personal emergency preparedness plan.
6. Identify the type of patients to recommend for hospital discharge in a disaster situation.

Psychosocial Integrity

7. Assess survivors for ability to adapt to the effects of disaster changes or traumatic events.
8. Provide support to the person and/or family in coping with life changes resulting from a disaster.

A **disaster** is commonly defined as an event in which illness or injuries exceed resource capabilities of a health care facility or community due to destruction and devastation. It can be either an internal or an external disaster.

TYPES OF DISASTERS

An *internal* disaster is any event inside a health care facility or campus that could endanger patients or staff. The event creates a need for evacuation or relocation. It often requires extra personnel and the activation of the facility's emergency preparedness and response plan (also called an *emergency management plan*). Examples of potential internal disasters include fire, explosion, and violence. Each health care facility develops policies and procedures for preventing these events through an organized security management plan. The most important outcome for any internal disaster is to maintain patient, staff, and visitor safety.

An *external* disaster is any event outside the health care facility or campus, somewhere in the community, which

requires the activation of the facility's emergency management plan. The number of facility staff is not adequate for the incoming emergency department (ED) patients. External disasters can be either natural, such as a hurricane, or technologic, such as a biologic terror attack.

Both internal and external disasters can result in many casualties, including death. Multi-casualty and mass casualty (disaster) events are not the same. The main difference is based on the scope and scale of the incident, considering the number and severity of victims or casualties involved. Both require specific response plans to activate necessary resources. In general, a **multi-casualty event** can be managed by a hospital using local resources; a **mass casualty event** overwhelms local medical capabilities and may require the collaboration of multiple agencies and health care facilities to handle the crisis (Smith, 2010). State, regional, and/or national resources may be needed to support the areas affected by the event. Trauma centers have a special role in all emergency preparedness activities because they provide a critical level of expertise in complex injury management.

CHART 12-1 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Nurse's Role in Responding to Health Care Facility Fires

- Remove any patient or staff from immediate danger of the fire or smoke.
- Discontinue oxygen for all patients who can breathe without it.
- For patients on life support, maintain their respiratory status manually until removed from the fire area.
- Direct ambulatory patients to walk to a safe location.
- If possible, ask ambulatory patients to help push wheelchair patients out of danger.
- Move bedridden patients from the fire area in bed, by stretcher, or in a wheelchair; if needed, have one or two staff members move patients on blankets or carry them.
- After everyone is out of danger, seek to contain the fire by closing doors and windows and using an ABC extinguisher (can put out any type of fire), if possible.
- Do not risk injury to you or staff members while moving patients or attempting to extinguish the fire.

To maintain ongoing disaster preparedness, hospital personnel participate in emergency training and drills regularly. In the United States, The Joint Commission (2008) mandates that hospitals have an emergency preparedness plan that is tested through drills or actual participation in a real event at least twice yearly. One of the drills or events must involve community-wide resources and an influx of actual or simulated patients to assess the ability of collaborative efforts and command structures. In addition, accredited health care organizations are required to take an “all-hazards approach” to disaster planning. Using this approach, preparedness activities must address *all credible threats* to the community that could result in a disaster situation. Disaster drills, then, are ideally planned based on a risk assessment that identifies the events most likely to occur in a particular community. For example, a flood is more likely in the Gulf of Mexico and an avalanche is more likely in ski areas of the Rocky Mountains.

Hospitals are not the only health care agencies that are required to practice disaster drills. Nursing homes and other long-term care (LTC) facilities are also mandated to have annual drills to prepare for mass casualty events. Part of the response plan must include a method for evacuation of residents from the facility in a timely and safe manner.

An evacuation plan is also part of fire prevention and preparedness plans for health care facilities. The Life Safety Code® published by the National Fire Protection Association provides guidelines for building construction, design, maintenance, and evacuation. Every health care facility is required to practice at least one fire drill or actual fire response once a year. Patient evacuation is not required if the event is a drill. All facility personnel are mandated to have training on fire prevention and responsiveness each year. [Chart 12-1](#) lists general guidelines for fire responsiveness and building evacuation to ensure safety.

IMPACT OF RECENT EXTERNAL DISASTERS

The events of September 11, 2001, changed hospital and community disaster planning efforts. With the shocking terrorist

FIG. 12-1 Hazardous materials (HAZMAT) training to decontaminate people exposed to toxic agents in an outdoor decontamination area.

attacks on the Twin Towers of the World Trade Center and the Pentagon and the actual and perceived threat of domestic terrorism including anthrax exposure that followed, hospital emergency preparedness concepts became much more fully integrated into the daily operations of emergency departments (EDs) by necessity. Weapons of mass destruction (WMD) rapidly became the focus of public health risk.

The term “NBC” was coined to describe nuclear, biologic, and chemical threats. In response, emergency medical services (EMS) agencies and hospitals upgraded their decontamination facilities, equipment, and all levels of personal protective gear to better protect staff. ED physician and nursing staff underwent hazardous materials (HAZMAT) training and learned how to recognize patterns of illness in patients who present for treatment that potentially indicate biologic terrorism agents, such as anthrax or smallpox ([Fig. 12-1](#)). Protocols for the pharmacologic treatment of infectious disease agents, as well as stockpiles of antibiotics and nerve agent antidotes, were made readily available.

The most immediate outcome of improving emergency preparedness after September 11 is that the ability to competently handle the more typical multi-casualty or mass casualty incident such as a bus crash, tornado, or building collapse has been greatly improved in many communities. However, disaster situations can still exceed the scope of usual day-to-day crisis operations, pointing to the necessity of well-defined regional and national emergency preparedness plans.

In 2005, Hurricane Katrina made landfall in Louisiana and other Gulf states as a category-4 storm and caused more than 1000 deaths and devastating environmental and property damage ([Fig. 12-2](#)). Volunteers from all over the United States, as well as local, regional, and federal agencies, took part in the large-scale disaster evacuation, rescue, and relief effort that severely challenged available resources and established disaster plans. Critical systems failed and were eventually re-established through coordination with multiple agencies and people to ensure that the most basic human needs were met ([Fig. 12-3](#)). Hurricane Katrina overwhelmed the existing emergency care system and caused the mobilization of a national mutual aid response on a level that had not been experienced in recent U.S. history.

FIG. 12-2 Property damage resulting from Hurricane Katrina in New Orleans.

FIG. 12-3 Temporary shelter set up for homeless victims of Hurricane Katrina in New Orleans.

Lessons learned from Hurricane Katrina, as well as recent worldwide incidents such as the earthquake in Haiti, tsunamis, and terrorist attacks, enable improved preparation and coordination of efforts that are beneficial for future disasters. These insights also can be applied to health care facility and community agency plans for pandemic infections, including influenza.

A pandemic leads a vast number of people to seek medical care, even the “worried well.” Though not yet ill, the “worried well” want evaluation, preventive treatment, or reassurance from a health care provider. A pandemic influenza outbreak, such as 2009–2010 swine flu outbreak caused by the H1N1 virus, raised significant concerns that the resource capabilities of the entire health care system could be overwhelmed and that community systems and critical supply chains could be severely damaged. Worker illness, absenteeism, and personal choices to remain quarantined to avoid being exposed to the illness negatively affect the number of health care staff available to care for patients. Fortunately, because of widespread vaccination programs and public information campaigns, the swine flu pandemic of 2009–2010 was well managed. Concern

remains that avian influenza A strain (H5N1), also known as “bird flu,” could pose a global pandemic threat if a gene mutation occurs to allow human-to-human spread. Because of the mass casualty nature of pandemic influenza, emergency preparedness planners must incorporate strategies to handle an influx of ill patients into the system as part of ongoing disaster readiness. Quarantine of selected nursing units or the entire hospital could become necessary, prompting closure until the risk has passed.

Common to all mass casualty events, the desired outcome of **emergency preparedness** is to outline ways to meet the extraordinary need for hospital beds, staff, drugs, personal protective equipment (PPE), supplies, and medical devices, such as mechanical ventilators (Casani & Romanosky, 2006). The U.S. government stockpiles critical equipment and supplies in case they are needed for a pandemic influenza outbreak. In addition, the Food and Drug Administration (FDA) approved the first vaccine to protect humans against H5N1 avian influenza virus (see [Chapter 25](#) for more information on emerging infections). Each state has its own specific emergency preparedness plan for pandemic influenza, including who would receive vaccines in a mass casualty event. Most of these plans are posted on the Internet.

EMERGENCY PREPAREDNESS AND RESPONSE

Mass Casualty Triage

Triage Process

A key process in any multi-casualty or mass casualty response is effective **triage** to rapidly sort ill or injured patients into priority categories based on their acuity and survival potential.

! NURSING SAFETY PRIORITY

Action Alert

In mass casualty or disaster situations, implement a military form of triage with the overall desired outcome of doing the greatest good for the greatest number of people (Smith, 2010). This means that patients who are critically ill or injured and might otherwise receive attempted resuscitation during usual operations may be triaged into an “expectant” or “black-tagged” category and allowed to die or not be treated until others received care.

Typical examples of black-tagged patients are those with massive head trauma, extensive full-thickness body burns, and high cervical spinal cord injury requiring mechanical ventilation. The rationale for this seemingly heartless decision is that limited resources must be dedicated to saving the most lives rather than expending valuable resources to save one life at the possible expense of many others.

Triage functions may be performed by EMS providers in the field, such as:

- Emergency medical technicians (EMTs) and paramedics
- Nurse and physician field teams who are called from the hospital to a disaster scene to assist EMS providers
- Nurse and physician hospital teams to assess and reassess incoming patients

Before going to the incident in the field, nurses, physicians, and support staff must have adequate training to prepare

them to recognize the risks in an unstable environment (Laskowski-Jones, 2010). Such risks can include the potential for structural collapse, becoming the secondary target of a terrorist attack, interpersonal violence in unsecured locales, and working in an environment in which contagious diseases and natural hazards are common (e.g., poisonous snake bites and mosquito-borne illnesses). Disaster workers must take measures such as obtaining prophylactic medications and vaccinations, having a personal evacuation plan, and ensuring access to necessary supplies and protective equipment so that they do not become victims as well.

The National Disaster Life Support Foundation offers Basic Disaster Life Support and Advanced Disaster Life Support training courses that include all essential aspects of disaster response and management. They include the core competencies of disaster management to all levels of health care professionals (Subbarao et al., 2008). In addition, the Federal Emergency Management Agency (FEMA) provides Community Emergency Response Team (CERT) training so that people are better prepared for disasters and are able to respond more self-sufficiently to incidents and hazard situations in their own communities. These courses include mass casualty triage education.

Triage Method

An important point to recognize is that triage concepts in a mass casualty incident differ from the “civilian triage” methods discussed in Chapter 10 that are practiced during usual emergency department operations (Table 12-1). Although disaster triage practices can vary widely based on local EMS protocols, some concepts are fairly universal. Most mass casualty response teams both in the field (at the disaster site) and in the hospital setting use a **disaster triage tag system** that categorizes triage priority by color and number (Smith, 2010):

- Emergent (class I) patients are identified with a red tag.
- Patients who can wait a short time for care (class II) are marked with a yellow tag.
- Nonurgent or “walking wounded” (class III) patients are given a green tag.
- Patients who are expected to die or are dead are issued a black tag (class IV).

TABLE 12-1 COMPARISON OF TRIAGE UNDER USUAL VERSUS MASS CASUALTY CONDITIONS

TRIAGE UNDER USUAL CONDITIONS	TRIAGE UNDER MASS CASUALTY CONDITIONS
Emergent (immediate threat to life)	Emergent or class I (red tag) (immediate threat to life)
Urgent (major injuries that require immediate treatment)	Urgent or class II (yellow tag) (major injuries that require treatment)
Nonurgent (minor injuries that do not require immediate treatment)	Nonurgent or class III (green tag) (minor injuries that do not require immediate treatment)
Does not apply	Expectant or class IV (black tag) (expected and allowed to die)

In general, *red-tagged* patients have immediate threats to life, such as airway obstruction or shock, and require immediate attention. *Yellow-tagged* patients have major injuries, such as open fractures with a distal pulse and large wounds that need treatment within 30 minutes to 2 hours. *Green-tagged* patients have minor injuries that can be managed in a delayed fashion, generally more than 2 hours. Examples of green-tag injuries include closed fractures, sprains, strains, abrasions, and contusions.

The green-tagged patients are often referred to as the “walking wounded”; they may actually evacuate themselves from the mass casualty scene and go to the hospital in a private vehicle. Green-tagged patients usually make up the greatest number in most large-scale multi-casualty situations. Therefore they can overwhelm the system if provisions are not made to handle them as part of the disaster plan. Also, because they often come to the hospital on their own, the hospital may not be able to determine how many actual casualties will arrive. A related concern is that green-tagged patients who self-transport may unknowingly carry contaminants from a nuclear, biologic, or chemical incident into the hospital environment with potentially disastrous consequences. ED staff must anticipate these issues and devise emergency response plans accordingly, including appropriate decontamination measures.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

The nurse is preparing to triage clients at the scene of an airplane crash. Which of these clients will the nurse identify as emergent?

- Young woman with closed fractures of her right leg and arm
- Older woman with abdominal bleeding who is dazed and confused
- Middle-aged man with third-degree burns over 90% of his body
- Young man with numerous bruises and superficial lacerations

Once patients are in the triage area of the hospital, they typically receive a special bracelet with a disaster number. Preprinted labels with this number can be applied to the patients’ chart forms and personal belongings. Digital photos may be used as part of the identification process in some systems. The standard hospital registration process and identification band can be applied after the patient’s identity is confirmed.

Automated tracking systems using infrared and radiofrequency technology are available in some emergency departments; these systems may be used to track a patient’s triage priority upon arrival, location, and process of care. The interactions the patient has with caregivers can also be tracked, an important safety strategy if the patient is later found to have contaminants or a disease that could pose a risk to staff members who had close contact and require decontamination or prophylaxis (Laskowski-Jones, 2008). These newer systems are valuable components of the hospital’s emergency preparedness infrastructure because they can rapidly portray the overall census and acuity of patients. They also enable ED leaders to determine how many casualties of a particular acuity level a hospital can safely accept from the incident scene in a disaster situation and to track contacts between patients and caregivers for management of actual or potential exposures to infectious or hazardous agents.

Notification and Activation of Emergency Preparedness/Management Plans

When the number of casualties exceeds the usual resource capabilities, a disaster situation exists. What may be a routine day in the emergency department of a large urban trauma center could be defined as a disaster for a small rural community hospital if the same number of patients were to arrive. Each facility, then, decides what a disaster situation is. Flexibility is needed because resources may change by time of day and by day of the week. For instance, hospitals typically have the fewest staff available after midnight on the weekend. An incident that occurs in this time frame may require activation of the emergency preparedness plan to bring extra resources into the hospital. The same incident during weekday business hours might be handled with on-site personnel alone without the need for activation of the plan.

Notification that a multi-casualty or mass casualty situation exists usually occurs by radio, cellular, or electronic communication between the ED and EMS providers at the scene. A state or regional emergency management agency may also notify the ED of the event. Each hospital has its own policy that specifies *who* has the authority to activate and *how* to activate the disaster or emergency preparedness plan. Group paging systems, telephone trees, and instant computer-based alert messages are the most common means of notifying essential personnel of a mass casualty incident or disaster.

A catastrophic event, such as a major earthquake or tornado, or a terrorist incident involving weapons of mass destruction (WMD) also requires volunteer assistance from all levels of health care providers in the region. In this case, the media may be contacted to broadcast messages to the health care community-at-large via television, radio, and electronic announcements. For such incidents, the National Guard, the American Red Cross, the public health department, various military units, a Medical Reserve Corps (MRC), or a Disaster Medical Assistance Team (DMAT) can be activated by state and federal government authorities.

An MRC is made up of a group of volunteer medical and public health care professionals, including physicians and nurses. They offer their services to health care facilities or to the community in a supportive or supplemental capacity during times of need such as a disaster or pandemic disease outbreak. This group may help staff hospitals or community health settings that face personnel shortages and establish first aid stations or special-needs shelters. The MRC may also set up an acute care center (ACC) in the community for patients who need acute care (but not intensive care) for days to weeks as a means to alleviate emergency department and hospital overcrowding (Casani & Romanosky, 2006).

A DMAT is a medical relief team made up of civilian medical, paraprofessional, and support personnel that is deployed to a disaster area with enough medical equipment and supplies to sustain operations for 72 hours (Merchant et al., 2010). DMATs are part of the National Disaster Medical System (NDMS) in the United States. They provide relief services ranging from primary health care and triage to evacuation and staffing to assist health care facilities that have become overwhelmed with casualties (Merchant et al., 2010). *Because licensed health care providers such as nurses act as federal employees when they are deployed, their professional licenses are recognized and valid in all states.*

Examples of what the NDMS provides are (U.S. Department of Health & Human Services, 2010):

- Disaster Mortuary Operational Response Teams (DMORTs) to manage mass fatalities
- National Veterinary Response Teams (NVRTs) for emergency animal care
- International Medical Surgical Response Teams (IMSuRTs) to establish fully functional field surgical facilities wherever they are needed in the world

Nurses can join these teams, complete the required training, and offer their expertise as part of a coordinated federal response team in times of critical need.

Hospital Emergency Preparedness: Personnel Roles and Responsibilities

Nurses play a major role in the emergency preparedness or emergency management plan. In the event of a disaster, the Hospital Incident Command System is established for organization and structure.

Hospital Incident Command System

The facility-level organizational model for disaster management is the **Hospital Incident Command System (HICS)**, which is a part of the National Incident Management System (NIMS) implemented by the Department of Homeland Security and the Federal Emergency Management Agency (FEMA) to standardize disaster operations. In this system, roles are formally structured under the hospital or long-term care facility incident commander with clear lines of authority and accountability for specific resources. Officers are named to oversee essential emergency preparedness functions such as public information, safety and security, and medical command. Chiefs are appointed to manage logistics, planning, finance, and operations as appropriate to the type and scale of the event. In turn, chiefs delegate specific duties to other departmental officers and unit leaders. The idea is to achieve a manageable span of control over the personnel or resources allocated to achieve efficiency (Sutingco, 2006). FEMA offers free courses on the NIMS model and HICS structure through their website (<http://training.fema.gov/IS/NIMS.asp>).

Because mass casualty events typically involve large numbers of people and can create a chaotic work environment, many EMS agencies and health care facilities use brightly colored vests with large lettering to help identify key leadership positions. Specific job action sheets are distributed to all personnel with leadership roles in HICS that pre-define reporting relationships and list prioritized tasks and responsibilities. The HICS personnel also establish an **emergency operations center (EOC)** or **command center** in a designated location with accessible communication technology. They then use their collective expertise to manage the overall incident (Sutingco, 2006). All internal requests for additional personnel and resources, as well as communication with field teams and external agencies, should be coordinated through the EOC to maintain unity of command.

The roles and responsibilities of health care personnel in a mass casualty event or disaster are defined within the institution's emergency response or preparedness plan (Table 12-2). Each plan can be as individual as the particular facility's operations. However, virtually all plans identify certain

TABLE 12-2 SUMMARY OF KEY PERSONNEL ROLES AND FUNCTIONS FOR EMERGENCY PREPAREDNESS AND RESPONSE PLAN

PERSONNEL ROLE	PERSONNEL FUNCTION
Hospital incident commander	Physician or administrator who assumes overall leadership for implementing the emergency plan
Medical command physician	Physician who decides the number, acuity, and resource needs of patients
Triage officer	Physician or nurse who rapidly evaluates each patient to determine priorities for treatment
Community relations or public information officer	Person who serves as a liaison between the health care facility and the media

key functions. For example, one of the primary roles in a hospital to be established at the onset of an incident is the role of a **hospital incident commander** who assumes overall leadership for implementing the institutional plan. This person is usually either a physician in the ED or a hospital administrator who has the authority to activate resources. The role can also be fulfilled by a nursing supervisor functioning as the on-site hospital administrator after usual business hours. The hospital incident commander's role is to take a global view of the entire situation and facilitate patient movement through the system. The commander brings in both personnel and supply resources to meet patient needs. For example, a hospital incident commander might dictate that all patients due to be discharged from an inpatient unit be moved to a lounge area immediately to free up hospital beds for mass casualty victims. He or she could also direct departments such as physical therapy or a surgical clinic to cancel their usual operations to convert the space into a minor treatment area. The incident commander assists in the organization of hospital-wide services to rapidly expand hospital capacity, recruit paid or volunteer staff, and ensure the availability of medical supplies.

Another typical role defined in hospital or other health care emergency preparedness plans is that of the **medical command physician**. He or she focuses on determining the number, acuity, and medical resource needs of victims arriving from the incident scene to the hospital and organizing the emergency health care team response to the injured or ill patients. Responsibilities include identifying the need for and calling in specialty-trained providers such as:

- Trauma surgeons
- Neurosurgeons
- Orthopedic surgeons
- Pulmonologists
- Plastic surgeons
- Burn surgeons
- Infectious disease physicians
- Industrial hygienists
- Radiation safety personnel

In smaller hospitals with limited specialty resources, the medical command physician might also help determine which patients should be transported out of the facility to a higher level of care or to a specialty hospital (e.g., burn center).

Closely affiliated with the medical command physician is the **triage officer**. This person is generally a physician in a large hospital who is assisted by triage nurses. When physician resources are limited, an experienced nurse may assume this role. The triage officer rapidly evaluates each person who presents to the hospital, even those who come in with triage tags in place. Patient acuity is re-evaluated for appropriate disposition to the area within the ED or hospital best suited to meet the patient's medical needs.

Many other roles and responsibilities can be defined within the institutional emergency response plan and may include the supply officer, the communications officer, the infection control officer, and the community relations/public information officer, to name a few. The community relations or public information officer is an especially important role to delineate in advance. Mass casualty incidents tend to attract a large amount of media attention. This staff member can draw media away from the clinical areas so that essential hospital operations are not hindered. He or she can also serve as the liaison between hospital administration and the media to release only appropriate and accurate information.

Role of Nursing in Health Care Facility Emergency Preparedness and Response

Nurses play key roles before, during, and after a disaster. Before an event, they contribute to developing internal and external emergency response plans, including defining specific nursing roles. Nurses take into account the security needs, communication methods, training, alternative treatment areas, staffing for high demand or surge situations, and requirements for resources, equipment, and supplies. They then test the plans by actively participating in disaster drills and evaluating the outcomes.

During an actual disaster, the ED charge nurse, trauma program manager, and other ED nursing leadership personnel act in collaboration with the medical command physician and triage officer to organize nursing and ancillary services to meet patient needs. Telephone trees may be activated to call in ED nurses who are not working or scheduled to work. ED areas are identified and prepared to stage, triage, resuscitate, and treat the disaster victims. Efforts are made to quickly discharge or admit other ED patients as appropriate to make room for the new arrivals. ED nurses apply principles of triage as disaster victims enter the system to prioritize care delivery and direct patients to the designated areas best suited to meet their needs.

Nursing roles in a disaster extend to all areas within a health care facility. The level of involvement is determined by the scope and scale of the disaster. In any mass casualty event, nurses from medical-surgical nursing units may be asked, in collaboration with the health care provider, to recommend patients for discharge to free up inpatient beds for disaster victims. Patients who are the most medically stable may be discharged early, including those who:

- Were admitted for observation and are not bedridden
- Are having diagnostic evaluations and are not bedridden
- Are soon scheduled to be discharged or could be cared for at home with support from family or home health services

- Have had no critical change in condition for the past 3 days
- Could be cared for in another health care facility, such as rehabilitation or long-term care

NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

A nurse needs to discharge two medical-surgical clients to make room for two victims of a tornado. Which of these clients could be discharged from the unit now? **Select all that apply.**

- A. 78-year-old with telemetry monitoring for chest pain last night
- B. 57-year-old who had a bowel resection for cancer 2 days ago
- C. 44-year-old who has received 3 days of IV antibiotics for pneumonia
- D. 61-year-old who had a thyroidectomy this morning
- E. 72-year-old who had a total hip replacement 2 days ago

General staff nurses also may be recruited to provide care for stable ED patients, thus allowing ED nurses to focus their efforts on aiding the mass casualty victims. Critical care unit nurses need to identify patients who can be transferred out of the unit to rapidly expand critical care bed capacity. In addition, they can supplement ED nurses in the resuscitation setting or assist in monitored care and transport to critical care units. Hospital and ED nurse leaders also typically direct the ancillary departments to deliver supplies, instrument trays, medications, food, and personnel to meet service demands.

Hospital staff of all levels may be required to alter their routine operations to accommodate a high volume of patients, including those with special needs such as decontamination, burn management, or quarantine. Emergency plans dictate specific actions by staff members, such as who should be called when the plan is activated, who should report, where to report, what supplies or equipment carts should be brought to a pre-designated location, and what type of paperwork or system should be implemented for patient identification in a large-scale event. Some staff may even have their roles changed completely. For example, nurses from the performance improvement department or case management may be reassigned to fulfill a clinical responsibility for a nursing unit. The key concept is that staff members are expected to remain flexible in a mass casualty situation and perform at their highest level to address the needs of both the health care system and the patients. The greatest good for the greatest number of people is still the organizing principle when considering roles and responsibilities in mass casualty events—not necessarily individual staff preferences. However, the safety of all patients is vital.

Creativity and flexibility of nursing leaders and nursing staff are essential to provide the staffing coverage necessary for a large-scale or extended incident. A **personal emergency preparedness plan** for each nurse can help in such situations. It should outline the preplanned specific arrangements that are to be made for childcare, pet care, and older adult care if the need arises, especially if the event prevents returning home for an extended period.

When called to respond to work during a mass casualty event, some nurses may experience ethical and moral conflict between their family obligations and professional responsibilities (Chaffee, 2006). The American Nurses Association's (ANA's) **Code of Ethics for Nurses with Interpretive Statements** (2001) does not offer clear guidance in this

NURSING SAFETY PRIORITY

Action Alert

Include emergency contact names, addresses, and telephone numbers to use in a crisis as part of a personal emergency preparedness plan. In addition, pre-assemble **personal readiness supplies** or **"go bag"** (disaster supply kit) for the home and automobile with clothing and basic survival supplies, which allows for a rapid response for disaster staffing coverage (Table 12-3). "Go bags" are needed for all members of the family, including pets, in the event the disaster requires evacuation of the community or people to take shelter in their own homes.

DECISION-MAKING CHALLENGE

Patient-Centered Care

A coastal town where you live is struck by an F5 hurricane. Buildings have collapsed, power has been lost, and local emergency services are overwhelmed. Two victims next door are trapped by debris in two different rooms of a house and need immediate attention: an awake but unresponsive older woman with blood partially obstructing her airway and an open fracture of her leg; and her pale, unconscious 20-year-old granddaughter who has a profuse, pulsatile hemorrhage from a radial artery laceration caused by flying broken glass. No one is available to assist you at the moment.

1. Which injured person will you attend to first and why?
2. What is your priority for emergency care in this situation?
3. Without adequate medical supplies, how will you use your creativity to care for each of these women?
4. If one of these patients dies while you are caring for the other one, how do you think you would cope with this situation?

TABLE 12-3 BASIC SUPPLIES FOR PERSONAL PREPAREDNESS (3-DAY SUPPLY)

- Backpack
- Clean clothing, sturdy footwear
- Potable water—1 gallon per person per day for at least 3 days
- Food—non-perishable, no cooking required
- Flashlight—battery powered; extra batteries and/or chemical light sticks
- Pocket knife or multi-tool
- Personal ID with emergency contacts and phone numbers, allergies, and medical information; lists of credit card numbers and bank accounts (keep in watertight container)
- Towel and washcloth; towelettes, soap, hand sanitizer
- Paper, pens, and pencils; regional maps
- Cell phone
- Sunglasses/eyewear
- Emergency blanket and/or sleeping bag and pillow
- Work gloves
- Personal first aid kit with over-the-counter (OTC) and prescription medications/vitamins
- Rain gear
- Roll of duct tape and plastic sheeting
- Radio—battery powered or hand-crank generator
- Toiletries (toothbrush and toothpaste, comb, brush, razor, shaving cream, mirror, feminine supplies, deodorant, shampoo, lip balm, sunscreen, insect repellent, toilet paper)
- Plastic garbage bags and ties, re-sealable plastic bags
- Matches in a waterproof container
- Whistle
- Household liquid bleach for disinfection

situation. Each person has to make a choice about whether to be involved in helping during the emergency or when to become involved.

EVENT RESOLUTION AND DEBRIEFING

When the last major casualties have been treated and no more are expected to arrive in numbers that could overwhelm the health care system, the incident commander considers “standing down” or deactivating the emergency response plan. However, although the casualties may have left the ED, other areas in the hospital may still be under stress and need the support of the supplemental resources provided by emergency plan activation. Before terminating the response, it is essential to ensure that the needs of the other hospital departments have been met and all are in agreement to resume normal operations.

A vital consideration in event resolution is staff and supply availability to meet ongoing operational needs. If nursing staff and other personnel were called in from home during their off hours or if they worked well beyond their scheduled shifts to meet patient and departmental needs, provision for adequate rest periods should be made. Exhaustion poses a risk not only to patient safety but also to the nurse when he or she must drive home. Sleeping quarters at the hospital might be necessary in this case, especially if the disaster event contributed to treacherous travel conditions.

Severe shortages of supplies also pose a threat to usual operations at the conclusion of a mass casualty incident. Taking inventory and restocking the ED are high priority assignments. Collaboration between the ED and the central supply department is essential to resolving stock availability problems. Instrument trays must be washed, packaged, and re-sterilized. Critical supplies that have been depleted from hospital stores must be reordered and delivered to the hospital quickly. Contracts with key vendors outlining emergency re-supply expectations and arrangements should be a part of the hospital’s overall emergency preparedness plan.

Two general types of **debriefing**, or formal systematic review and analysis, occur after a mass casualty incident or disaster. The first type entails bringing in critical incident stress debriefing (CISD) teams to provide sessions for small groups of staff to promote effective coping strategies. The second type of debriefing involves an administrative review of staff and system performance during the event to determine whether opportunities for improvement in the emergency management plan exist.

Critical Incident Stress Debriefing

CISD is only one component of a much broader critical incident stress management (CISM) program. CISM programming addresses pre-crisis through post-crisis interventions for small to large groups, including communities. After working through the turmoil and the emotional impact of the incident as well as the aftermath, the staff may find it difficult to “get back to normal.” Without intervention during *and* after the emergency, they may develop post-traumatic stress disorder (PTSD). PTSD can lead to multiple

CHART 12-2 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Preventing Staff Post-Traumatic Stress Disorder (PTSD) During a Mass Casualty Event

- Use available counseling.
- Encourage and support co-workers.
- Monitor each other’s stress level and performance.
- Take breaks when needed.
- Talk about feelings with staff and managers.
- Drink plenty of water, and eat healthy snacks for energy.
- Keep in touch with family, friends, and significant others.
- Do not work for more than 12 hours per day.

Adapted from Papp, E. (2005). Preparing for disasters: Helping yourself as you help others. *AJN*, 105(5), 112.

characteristic psychological and physical effects, including flashbacks, avoidance, less interest in previously enjoyable events, and detachment, as well as rapid heart rate and insomnia. People suffering from PTSD can have great difficulty relating in their usual way to family and friends. Ultimately, professional “burnout” can stem from the inability to cope with the stress effectively. Occupational health nurses can serve as valuable resources to disaster response workers in promoting strategies for physical, emotional, and spiritual health (Tomczyk et al., 2008). [Chart 12-2](#) lists recommendations proposed by several national organizations to help prevent PTSD during the emergency situation.

A CISD team comprises two or three specially trained people who come together quickly when called to deal with the emotional needs of health care team members after a particularly devastating or disturbing incident. The team leader typically has background in a mental health/behavioral health field. The co-leader is ideally a peer of the group being debriefed. Thus, if nurses are debriefed, then a nurse member of the CISD team is generally assigned to the session. CISD-trained physicians, police, firefighters, EMTs, and paramedics may also be used, depending on the needs of the group. The third member of the team is known as the “doorkeeper.” This person is responsible for keeping inappropriate people out (e.g., media, spectators) and talking with anyone who leaves the session early in an effort to have him or her return or accept follow-up (Mitchell et al., 2003b). Staff involved in the incident need protected time to undergo stress debriefing, which generally lasts from 1 to 3 hours per session.

Typical “ground rules” for stress debriefing include strict confidentiality of information shared during the session and unconditional acceptance of the thoughts and feelings expressed by people within the group. The usual arrangement for the most effective group interaction is a circular configuration of chairs in a private setting. Food should be available so that hunger is not a distraction. CISD group leaders encourage group discussion through asking a series of questions designed to get everyone involved tell his or her own story about the incident and explain the personal impact. The group leaders enable participants to place the incident into perspective and dispel any feelings of blame or guilt. They also educate participants about self-care concepts and coping strategies to use immediately. People who require more than

a CISM session may need referral for mental health/behavioral health counseling. Research efforts using meta-analysis techniques have produced mixed results regarding the efficacy of CISM. However, the technique is thought to be clinically effective (Mitchell et al., 2003b).

Administrative Review

The second type of debriefing is an administrative evaluation directed at analyzing the hospital or agency response to an event while it is still in the forefront of the minds of everyone who participated in it. The goal of this type of debriefing is to discern what went right and what went wrong during activation and implementation of the emergency preparedness plan so that changes can be made. Typically, representatives from all groups that were involved in the incident come together soon after plan activation has been discontinued. They each are given an opportunity to hear and express both positive and negative comments related to their experiences with the event. Then, in the days after the plan activation, written critique forms are also solicited to gain additional information after participants have had time to consider their overall impressions of the response as well as the impact it had on their respective departments or clinical areas.

Although drills are important, implementing the emergency preparedness plan during an actual mass casualty event is the most effective means of “reality testing” the plan’s utility. Feedback provided by participants can be used to modify or revise the plan and create new processes in preparation for future events.

ROLE OF NURSING IN COMMUNITY EMERGENCY PREPAREDNESS AND RESPONSE

During a community disaster, nurses and other emergency personnel may be needed for triage, first aid/emergency care, and shelter assistance. The first action of first-responders in a disaster is to remove people from danger, both the injured and uninjured. This job is typically managed by firefighters and other disaster-trained emergency personnel; nurses are not usually involved in this process.

After removal from danger, victims are triaged by health care personnel as described earlier in this chapter. Following triage, nurses often provide on-site first aid and emergency care. They may also be involved in teaching and supervising volunteers. The American Red Cross sets up shelters for people who have lost their homes or have been evacuated from their homes.

Nurses may also need to teach those living temporarily in shelters about procedures that will be needed when they return home. For example, safe drinking water may not be available for several days or longer. Community residents may need to boil their water for 5 to 10 minutes before drinking. If electricity and gas are not available, an outdoor grill or camp stove can be used. As alternative procedures, commercial water purification tablets or 10 to 20 drops of chlorine bleach added to a gallon of water will make the water safe to drink.

Human waste management creates another challenge if toilets do not flush. If not managed safely, enteric pathogens

spread disease. A toilet bowl or bucket lined with a plastic bag can be used for human waste. To sanitize it and provide odor control, chlorine bleach can be added and the bag tied and sealed. Portable toilet chemicals or chlorinated lime may be used as alternatives. To prevent a toxic gas reaction, remind residents not to mix any chemicals. Treated human waste bags can be buried in the ground. Emphasize the importance of handwashing with soap and water or using a hand sanitizer to prevent disease transmission.

PSYCHOSOCIAL RESPONSE OF SURVIVORS TO MASS CASUALTY EVENTS

One of the most important roles of the nurse after a community disaster is health assessment, including psychosocial health. Experiencing a disaster can produce both immediate and long-lasting psychosocial effects in people personally affected by the event. Depending on the nature and magnitude of the incident, survivors experience the tragic loss of loved ones, property, and valued possessions. They and their family members may have suffered injuries or illnesses brought about by the catastrophe. Lifestyles, roles, and routines are drastically altered, preventing people from achieving any sense of normalcy in the hours, the days, and perhaps even the weeks and months that follow a disaster. Coping abilities in survivors are severely stressed, leading to many individual responses that can range from functional and adaptive behaviors to maladaptive coping.

Survivors have to confront feelings of vulnerability resulting from the devastating event, knowing that it could occur again—a particularly relevant issue for people who live in areas prone to acts of terrorism or to natural disasters. The decision—be it voluntary or involuntary—to abandon a family home or geographic region and then relocate to a “safe” area either temporarily or permanently results in a further sense of loss and grief. Some people may feel guilty about living through an event that caused so many others to die. The range of intense emotions can appear as physical illness, as well as psychological and social dysfunction.

When helping people in crisis after a mass casualty event, be calm and reassuring. Establish rapport through active listening and honest communication. Survivors benefit from talking about their experiences and being helped as they work to problem-solve. Offer choices whenever possible to help survivors gain a sense of personal control. Help survivors adapt to their new surroundings and routines through simple, concrete explanations. Convey caring behaviors, and provide a sense of safety and security to the best extent possible.

A disaster may cause some survivors to develop post-traumatic stress disorder (PTSD), which can potentially last for a lifetime. People who are unable to sleep, are easily startled, have “flashbacks” to relive the disaster, or report “feeling numb” 2 weeks or more after a disaster or traumatic event are at risk for PTSD (Hyer & Brown, 2008).

Nurses caring for survivors with these manifestations should perform further assessment. One tool that can be used to assess survivor response to a disaster is the Impact of Event Scale—Revised (IES-R). The IES-R is a 22-item

self-administered questionnaire including several subscales, such as avoidance. Before giving the tool, determine the patient's reading level because it is written at a 10th-grade reading level. The tool should not be used for patients with short-term memory loss. For that reason, many older survivors are often not adequately assessed for post-disaster PTSD (Hyer & Brown, 2008). However, assess all older survivors of a disaster for this complication when possible.

NURSING SAFETY PRIORITY

Action Alert

A high score on any IES-R subscale indicates a need for further evaluation and counseling. Refer the patient to a social worker or qualified mental health counselor. A high score on all subscales requires referral to a psychiatrist or clinical psychologist to evaluate the possibility of current or past trauma, such as abuse or neglect.

GET READY FOR THE NCLEX® EXAMINATION!

KEY POINTS

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- All medical centers must have an emergency preparedness and response team in case of mass casualty (disaster).
- If a fire occurs in a health care facility, follow agency policy and procedures; use the guidelines in [Chart 12-1](#) to respond to a fire in any facility.
- The typical triage system for a mass casualty situation includes an additional category for those patients allowed to die (black-tagged) (see [Table 12-1](#)).
- Special roles are assigned in a mass casualty incident as identified in [Table 12-2](#).
- In the emergency department, assist in determining the need for initiating the emergency preparedness plan based on available resources, including staffing.
- Be prepared for an emergency, including a plan for child, pet, and older adult care; have a “to go” bag, or disaster supply kit, packed for both the automobile and the home (see [Table 12-3](#)).

- Two types of debriefing occur after a mass casualty event or period—critical incident stress debriefing and an administrative review or evaluation.
- Nurses have important roles in preparing for, managing, and debriefing after an internal health care facility disaster.
- Nurses play a major role in triage, first aid and emergency care, and shelter assistance in external community disasters.

Psychosocial Integrity

- Assess families and other survivors for their reaction to temporary or permanent loss as a result of a mass casualty event, including post-traumatic stress disorder (PTSD).
- Provide emotional support by encouraging relaxation, listening to survivor feelings, and referring for appropriate counseling.
- Be honest with victims and their families, and help them adapt to their changed or new surroundings.
- Take precautions to prevent staff from developing post-traumatic stress disorder (PTSD) as outlined in [Chart 12-2](#).

Management of Patients with Fluid, Electrolyte, and Acid-Base Imbalances

CHAPTER 13

Assessment and Care of Patients with Fluid and Electrolyte Imbalances

Key Points

Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Assess the patient with a fluid or electrolyte imbalance for falls, especially older adults.
2. Use safety precautions to prevent injury or death when administering parenteral potassium-containing solutions.
3. Supervise the oral fluid therapy and intake and output measurement aspects of care delegated to unlicensed assistive personnel.

Health Promotion and Maintenance

4. Teach healthy adults and patients how to prevent dehydration.
5. Assess patients for factors that increase the risk for fluid and electrolyte imbalances, especially for older adults.
6. Teach patients at risk for fluid or electrolyte imbalances as a result of drug therapy about the manifestations of the imbalance.

Physiological Integrity

7. Explain the relationship between weight gain or loss and fluid imbalances.
8. Apply knowledge of the anatomic and physiologic responses to aging when assessing hydration status of an older adult.
9. Use laboratory data and clinical manifestations to determine the presence of fluid or electrolyte imbalances.
10. Interpret blood chemistry laboratory results to determine whether the patient has a fluid or electrolyte imbalance and to determine effectiveness of interventions.
11. Assess the breathing effectiveness of any patient with skeletal muscle weakness from an electrolyte imbalance.
12. Prioritize interventions for patients who have dehydration or fluid overload.
13. Prioritize interventions for patients who have specific electrolyte imbalances.

HOMEOSTASIS

Proper functioning of all body systems requires a balance of fluids and electrolytes. The body works best when these substances are kept within a narrow range of normal. For example, no body system works well if 2 liters of blood volume are gained or lost. To keep conditions as close to normal as possible (a situation called **homeostasis**), the body has many control actions (**homeostatic mechanisms**) to prevent dangerous changes.

An important area for homeostasis is maintaining the body's normal fluid volume and composition. Water is the most common substance in the body, making up about 55% to 60% of total body weight for healthy younger adults and 50% to 55% of total body weight for healthy older adults. This water (fluid) is divided into two main spaces or compartments—the fluid outside the cells, which is the **extracellular fluid (ECF)**; and the fluid inside the cells, which is the **intracellular fluid (ICF)**. The ECF space contains about one third (about 15 L) of the total body water. The ECF includes **interstitial fluid** (fluid between cells, sometimes called the “third space”); blood, lymph, bone, and connective tissue water; and the transcellular fluids. **Transcellular fluids** are the fluids in special body spaces and include cerebrospinal fluid, synovial fluid, peritoneal fluid, and pleural fluid. ICF contains the remaining two thirds (about 25 L) of total body water. Fig. 13-1 shows the normal distribution of total body water.

Water is needed to deliver dissolved nutrients, electrolytes, and other substances to all organs, tissues, and cells. In the healthy adult, the volume of water in the fluid compartments remains within the normal range although the water moves constantly between compartments. Changes in either the amount of water or the amount of electrolytes in body fluids can affect the functioning of all cells, tissues, and organs. *For proper function, the volume of all body fluids and the types and amount of dissolved substances must be carefully balanced.*

ANATOMY AND PHYSIOLOGY REVIEW

PHYSIOLOGIC INFLUENCES ON FLUID AND ELECTROLYTE BALANCE

Body fluids are composed of water and particles dissolved or suspended in water. The **solvent** is the water portion of fluids. **Solutes** are the particles dissolved or suspended in the water.

FIG. 13-1 Normal distribution of total body water in adults.

Solutes vary in type and amount from one fluid space to another. When solutes express an overall electrical charge, they are known as **electrolytes**. Body function depends on keeping the correct balance of fluid and electrolytes within each body fluid space.

Three processes are important to control normal fluid and electrolyte balance, and they work together to maintain balance so the internal environment remains stable even when the external environment changes. These processes are filtration, diffusion, and osmosis. They determine how, when, and where fluids and particles move across cell membranes.

Filtration

Physiologic Action

Filtration is the movement of fluid through a cell or blood vessel membrane because of hydrostatic pressure differences on both sides of the membrane. Filtration occurs because of differences in water volume pressing against confining walls.

Fluid weight in a confined space is related to the amount of fluid present in that area. Water molecules in a confined space constantly press outward against the confining walls. This pressing of water molecules is **hydrostatic pressure**. It is a “water-pushing” pressure, because it is the force that pushes water outward from a confined space through a membrane (Fig. 13-2).

The amount of water in any body fluid space determines the hydrostatic pressure of that space. Blood, a fluid that is “thicker” than water (more **viscous**), is confined within the blood vessels. Blood has hydrostatic pressure because of its weight and volume. An additional factor that affects blood hydrostatic pressure in arteries is the pumping action of the heart. This action has little impact on the hydrostatic pressure in the capillaries and veins.

The hydrostatic pressures of two fluid spaces can be compared whenever a porous (**permeable**) membrane separates the two spaces. If the hydrostatic pressure is the same in both fluid spaces, there is no pressure difference between the two spaces and the hydrostatic pressure is now at **equilibrium**. If the hydrostatic pressure is not the same in both spaces, **dis-equilibrium** exists. This means that the two spaces have a graded difference (**gradient**) for hydrostatic pressure: one space has a higher hydrostatic pressure than the other. *The human body constantly seeks equilibrium.* When a gradient exists, water movement (filtration) occurs until the hydrostatic pressure is the same in both spaces (see Fig. 13-2).

When nothing stops it, water moves through the membrane (**filters**) from the space with higher hydrostatic pressure to the space with lower pressure. This filtration continues only as long as the hydrostatic pressure gradient exists. Equilibrium is reached when enough fluid leaves one space and enters the other space to make the hydrostatic pressure in both spaces equal. At this point, water molecules may be exchanged evenly between two spaces in equilibrium but no net further filtration of fluid occurs. Neither space gains or loses water molecules, and the hydrostatic pressure in both spaces remains the same.

Clinical Significance

Blood pressure is an example of a hydrostatic filtering force. It moves whole blood from the heart to capillaries where filtration can occur to exchange water, nutrients, and waste

FIG. 13-2 The process of filtration.

FIG. 13-3 The basic structure of a capillary.

products between the blood and the tissues. One factor that determines whether fluid leaves the blood vessels and enters the tissue spaces (*interstitial fluid*) is the difference between the hydrostatic pressure of capillary blood and that of the interstitial fluid.

Capillaries are only one cell layer thick, making a thin “wall” to hold blood in the capillaries. Large spaces (**pores**) in the capillary membrane help water filter freely when a hydrostatic pressure gradient is present (Fig. 13-3).

Edema (tissue swelling with fluid collection) develops with changes in normal hydrostatic pressure differences, such as in patients with right-sided heart failure. In this condition, the volume of blood in the right side of the heart increases greatly because the right ventricle is too weak to pump blood efficiently into the pulmonary blood vessels. As blood backs up into the venous system, venous hydrostatic pressure rises, which then causes capillary hydrostatic pressure to rise until it is higher than the hydrostatic pressure in the interstitial space. As a result, excess filtration of fluid from the capillaries into the interstitial tissue space occurs, forming visible edema.

Diffusion

Physiologic Action

Diffusion is the free movement of particles (solute) across a permeable membrane from an area of higher concentration to an area of lower concentration (down a *concentration gradient*). This action controls the movement of solute particles in solution across various body membranes.

The diffusion of particles into and out from cells and fluid spaces occurs using the energy generated by the vibration of single molecules. This motion is totally random, allowing molecules to bump into each other within a confined space. Each collision increases the speed of particle movement.

As a result of the collisions, molecules in a solution spread out evenly through the available space. They move from an area of higher amounts (concentration) of molecules to an area of lower amounts until an equal amount is present in all areas. The number of collisions is related to the amount of molecules in a confined space. Fluid spaces with many particles have more collisions and faster particle movement than spaces with fewer particles.

A concentration gradient exists when two fluid spaces have different amounts of the same type of particles. Particle collisions cause them to move down the concentration gradient. Any membrane that separates two spaces is struck repeatedly by particles. When the particle strikes a pore in the membrane that is large enough for it to pass through, diffusion occurs (Fig. 13-4). The chance of any single particle hitting the membrane and going through a pore is much greater on the side of the membrane with a higher solute particle concentration.

The speed of diffusion is related to the difference in amount of particles (concentration gradient) between the two sides of the membrane. The degree of difference is the *steepness* of the gradient: the larger the concentration difference between the two sides, the steeper the gradient. Diffusion is more rapid when the gradient is steeper (just as a ball

FIG. 13-4 Diffusion of solute particles through a permeable membrane from an area of higher solute concentration to an area of lower solute concentration until an equilibrium is reached.

rolls downhill more rapidly when the hill is steep than when the hill is nearly flat). Particles move from the fluid space with a higher concentration of solute particles to the fluid space with a lower concentration of solute particles.

Diffusion of particles continues as long as a concentration gradient exists between the two sides of the membrane. When the concentration of solute particles is the same on both sides of the membrane, the particles are in equilibrium and only an equal exchange of particles continues.

Clinical Significance

Diffusion is important in the transport of most electrolytes and other particles through cell membranes. Unlike capillary membranes, which permit the diffusion of most small-size particles down a gradient, cell membranes are *selective* in which particles can diffuse. They permit diffusion of some particles but not others. Some particles cannot move across a cell membrane, even when a steep “downhill” gradient exists, because the membrane is **impermeable** (not open) to that particle. For these particles, the concentration gradient is maintained across the membrane.

Impermeability and special transport systems cause differences in the amounts of specific particles from one fluid space to another. For example, usually the fluid outside the cell (the extracellular fluid [ECF]) has ten times more sodium ions than the fluid inside the cell (the intracellular fluid [ICF]). This extreme difference is caused by cell membrane impermeability to sodium and by special “sodium pumps” that move any extra sodium present inside the cell out of the cell “uphill” against its concentration gradient and back into the ECF.

In some instances, diffusion cannot occur without help, even down steep concentration gradients, because of selective membrane permeability. One example is glucose. Even though the amount of glucose may be much higher in the ECF than in the ICF (creating a steep gradient for glucose), glucose cannot cross most cell membranes without the help

of insulin. When insulin is present, it binds to insulin receptors on cell membranes, which then makes the membranes much more permeable to glucose. As a result, glucose can cross the cell membrane down its concentration gradient until equilibrium of glucose concentration is achieved.

Diffusion across a cell membrane that requires the assistance of a membrane-altering system (e.g., insulin) is called **facilitated diffusion** or **facilitated transport**. This type of movement is still a form of diffusion.

Osmosis

Physiologic Action

Osmosis is the movement of water only through a selectively permeable (*semipermeable*) membrane. For osmosis to occur, a membrane must separate two fluid spaces and one space must have particles that cannot move through the membrane. (The membrane is impermeable to this particle.) Some of the reasons a membrane may be impermeable to a particle are that the particle is too large or that it expresses an electrical charge. A concentration gradient of this particle must also exist. Because the membrane is impermeable to these particles, they cannot cross the membrane but water molecules can. (Usually water can *always* move through a cell membrane.)

For the fluid spaces to have equal concentrations of the particle, the water molecules move down their concentration gradient from the side with the higher concentration of water molecules (and thus a lower concentration of particles along with a greater hydrostatic pressure) to the side with the lower concentration of water molecules (and a higher concentration of particles along with a lower hydrostatic pressure). This movement continues until both spaces contain the same proportions of particles to water. Dilute (less concentrated) fluid has fewer particles and more water molecules than the more concentrated fluid. Thus water moves by osmosis down its hydrostatic pressure gradient from the dilute fluid to the more concentrated fluid until a concentration equilibrium occurs (Fig. 13-5).

At this point, the concentrations of particles in the fluid spaces on both sides of the membrane are equal even though the total amounts of particles and volumes of water are different. *The concentration equilibrium occurs by the movement of water molecules rather than the movement of solute particles.*

Particle concentration in body fluids is the major factor that determines whether and how fast osmosis and diffusion occur. This concentration is expressed in milliequivalents per liter (mEq/L), millimoles per liter (mmol/L), and milliosmoles per liter (mOsm/L). **Osmolarity** is the number of milliosmoles in a *liter* of solution; **osmolality** is the number of milliosmoles in a *kilogram* of solution. The normal osmolality value for plasma and other body fluids ranges from 270 to about 300 mOsm/L. The body functions best when the osmolality of the fluids in all body fluid spaces is close to 300 mOsm/L. When all body fluids have this particle concentration, the body fluids are **isosmotic** to each other. Another term with the same meaning is **isotonic** (also called **normotonic**).

Fluids with osmolalities greater than 300 mOsm/L are **hyperosmotic**, or **hypertonic**, compared with isosmotic fluids. These fluids have a *greater* osmotic pressure than do

FIG. 13-5 The process of osmosis to generate a concentration equilibrium (but not a volume equilibrium) for a solute particle that cannot move through a cell membrane.

isotonic fluids and tend to pull water from the isotonic fluid space into the hypertonic fluid space until an osmotic balance occurs. If a hypertonic IV solution (e.g., 2% saline) were infused into a patient with normal ECF osmolarity, the infusing fluid would make the person's blood hypertonic. To balance this situation, the interstitial fluid would be pulled into the circulation in an attempt to dilute the blood osmolarity back to normal. As a result, the interstitial volume would shrink and the plasma volume would expand.

Fluids with osmolarities of less than 270 mOsm/L are **hypo-osmotic**, or **hypotonic**, compared with isotonic fluids. Hypo-osmolar fluids have a *lower* osmotic pressure than isotonic fluids, and water is pulled from the hypo-osmotic fluid space into the isotonic fluid space.

Solubility is how well a particle type dissolves in water. Fluids that have particles with greater solubility have higher osmotic pressures than fluids with insoluble particles.

Amount of membrane available for osmosis affects the speed of osmosis. More membrane increases the chances that water molecules will hit the membrane at a point where penetration is possible and thus increases the speed of osmosis.

Clinical Significance

Osmosis and filtration act together at the capillary membrane to maintain both extracellular fluid (ECF) and intracellular fluid (ICF) volumes within their normal ranges. The thirst mechanism is an example of how osmosis helps maintain homeostasis. The feeling of thirst is caused by the activation of cells in the brain that respond to changes in ECF osmolarity. These cells are so sensitive to changes in ECF osmolarity that they are called *osmoreceptors*. When a person loses body

water but most of the particles remain, such as through excessive sweating, ECF volume is decreased and osmolarity is increased (a hypertonic condition exists). The cells in the thirst center shrink as water moves from the cells into the hypertonic ECF. The shrinking of these cells triggers a person's awareness of thirst and increases the urge to drink. Drinking replaces the amount of water lost through sweating and dilutes the ECF osmolarity, restoring it to normal. *It is important to remember that the thirst mechanism is less sensitive in older adults, making them more at risk for dehydration.*

FLUID BALANCE

BODY FLUIDS

Fluid balance is closely linked to and affected by electrolyte concentrations. [Table 13-1](#) lists the normal ranges of the major serum electrolytes. [Chart 13-1](#) lists the normal electrolyte values for people older than 60 years.

A person's age, gender, and amount of fat affect the amount and distribution of body fluids. An older adult has less total body water than a younger adult. [Chart 13-2](#) discusses age-related changes in fluid balance. An obese person has less total water than a lean person of the same weight because fat cells contain almost no water.

Body fluids are constantly filtered and replaced as fluid balance is maintained through intake and output. The total amount of water within each fluid space is stable, but individual water molecules move continually among all spaces.

TABLE 13-1 MAJOR SERUM ELECTROLYTE CONCENTRATIONS AND SIGNIFICANCE OF ABNORMAL VALUES

ELECTROLYTE	REFERENCE RANGE	INTERNATIONAL RECOMMENDED UNITS	SIGNIFICANCE OF ABNORMAL VALUES
Sodium (Na ⁺)	136-145 mEq/L	136-145 mmol/L	<i>Elevated:</i> Hypernatremia; dehydration; kidney disease; hypercortisolism <i>Low:</i> Hyponatremia; fluid overload; liver disease; adrenal insufficiency
Potassium (K ⁺)	3.5-5.0 mEq/L	3.5-5.0 mmol/L	<i>Elevated:</i> Hyperkalemia; dehydration; kidney disease; acidosis; adrenal insufficiency; crush injuries <i>Low:</i> Hypokalemia; fluid overload; diuretic therapy; alkalosis; insulin administration; hyperaldosteronism
Calcium (Ca ²⁺)	9.0-10.5 mg/dL	2.25-2.75 mmol/L	<i>Elevated:</i> Hypercalcemia; hyperthyroidism; hyperparathyroidism <i>Low:</i> Hypocalcemia; vitamin D deficiency; hypothyroidism; hypoparathyroidism; kidney disease; excessive intake of phosphorus-containing foods and drinks
Chloride (Cl ⁻)	98-106 mEq/L	98-106 mmol/L	<i>Elevated:</i> Hyperchloremia; metabolic acidosis; respiratory alkalosis; hypercortisolism <i>Low:</i> Hypochloremia; fluid overload; excessive vomiting or diarrhea; adrenal insufficiency; diuretic therapy
Magnesium (Mg ²⁺)	1.3-2.1 mEq/L	0.65-1.05 mmol/L	<i>Elevated:</i> Hypermagnesemia; kidney disease; hypothyroidism; adrenal insufficiency <i>Low:</i> Hypomagnesemia; malnutrition; alcoholism; ketoacidosis
Phosphorus (P)	3.0-4.5 mg/dL	0.97-1.45 mmol/L	<i>Elevated:</i> Hyperphosphatemia; kidney disease; hypoparathyroidism; acidosis; hypocalcemia <i>Low:</i> Hypophosphatemia; chronic antacid use; hyperparathyroidism; hypercalcemia; vitamin D deficiency; alcoholism; malnutrition

Data from Pagana, K., & Pagana, T. (2010). *Mosby's manual of diagnostic and laboratory tests* (4th ed.). St. Louis: Mosby.

CHART 13-1 NURSING FOCUS ON THE OLDER ADULT

Normal Plasma Electrolyte Values for People Older Than 60 Years

ELECTROLYTE	REFERENCE RANGE		INTERNATIONAL RECOMMENDED UNITS	
	60-90 YEARS	>90 YEARS	60-90 YEARS	>90 YEARS
Calcium (Ca ²⁺)	9.0-10.5 mg/dL	8.2-9.6 mg/dL	2.2-2.75 mmol/L	2.05-2.40 mmol/L
Chloride (Cl ⁻)	98-106 mEq/L	98-111 mEq/L	98-106 mmol/L	98-111 mmol/L
Magnesium (Mg ²⁺)	1.3-2.1 mEq/L	1.3-2.1 mEq/L	0.65-1.05 mmol/L	0.65-1.05 mmol/L
Phosphorus (P)	3.0-4.5 mg/dL	3.0-4.5 mg/dL	0.97-1.45 mmol/L	0.97-1.45 mmol/L
Potassium (K ⁺)	3.5-5.0 mEq/L	3.5-5.0 mEq/L	3.5-5.0 mmol/L	3.5-5.0 mmol/L
Sodium (Na ⁺)	136-145 mEq/L	132-146 mEq/L	136-145 mmol/L	132-146 mmol/L

Data for adults 60 to 90 years from Pagana, K., & Pagana, T. (2010). *Mosby's manual of diagnostic and laboratory tests* (4th ed.). St. Louis: Mosby.

Data for adults >90 years from Tietz, N.W. (Ed.). (1995). *Clinical guide to laboratory tests* (3rd ed.). Philadelphia: Saunders.

CHART 13-2 NURSING FOCUS ON THE OLDER ADULT

Impact of Age-Related Changes on Fluid Balance

SYSTEM	CHANGE	RESULT
Skin	Loss of elasticity Decreased turgor Decreased oil production	Skin becomes an unreliable indicator of fluid status, especially the back of the hand Dry, easily damaged skin
Kidney	Decreased glomerular filtration Decreased concentrating capacity	Poor excretion of waste products Increased water loss, increasing the risk for dehydration
Muscular	Decreased muscle mass	Decreased total body water Greater risk for dehydration
Neurologic	Diminished thirst reflex	Decreased fluid intake, increasing the risk for dehydration
Endocrine	Adrenal atrophy	Poor regulation of sodium and potassium, predisposing the patient to hyponatremia and hyperkalemia

TABLE 13-2 ROUTES OF FLUID INGESTION AND EXCRETION

INTAKE	OUTPUT
Measurable	
Oral fluids	Urine
Parenteral fluids	Emesis
Enemas*	Feces
Irrigation fluids*	Drainage from body cavities
Not Measurable	
Solid foods	Perspiration
Metabolism	Vaporization through the lungs

*Measured by subtracting the amount returned from the amount instilled.

WOMEN'S HEALTH CONSIDERATIONS

Women of any age have less total body water than men of similar sizes and ages. This difference is because men have more muscle mass than women and because women have more body fat. (Muscle cells contain mostly water, and fat cells have little water.) This difference in water distribution may be responsible for differences seen in women's and men's responses to drugs.

As a result, water in all spaces is exchanged continually while maintaining constant fluid volume.

Fluid intake is regulated through the thirst drive. Fluids enter the body mainly as liquids (Table 13-2). Solid foods also contain up to 85% water, allowing some fluid to enter the body with ingested solid foods.

A rising blood osmolarity or a decreasing blood volume triggers the sensation of thirst. Sensations such as mouth dryness or the thought that a person has not had a drink recently also triggers the thirst drive. An adult drinks an average of 1500 mL of fluid per day and ingests an additional 800 mL of fluid from food.

Fluid loss occurs through several routes (see Table 13-2). Of all the water loss pathways, the kidney is the most important and the most sensitive. Water loss by the kidney is regulated and is adjustable. The volume of urine excreted daily varies depending on the amount of fluid taken in and the body's need to conserve fluids.

The minimum amount of urine per day needed to excrete toxic waste products is 400 to 600 mL. This minimum volume is called the **obligatory urine output**. If the 24-hour urine output falls below the obligatory output amount, wastes are retained and can cause lethal electrolyte imbalances, acidosis, and a toxic buildup of nitrogen.

The ability of the kidneys to make either concentrated or very dilute urine helps maintain fluid balance. The kidney works with various hormones to maintain fluid balance when extracellular fluid concentrations, volumes, or pressures change.

Other normal water loss occurs through the skin, the lungs, and the intestinal tract. Water losses also can result from salivation, drainage from fistulas and drains, and GI suction.

Water loss from the skin, lungs, and stool is called **insensible water loss**, because the body has no mechanisms to control this loss. The amount lost can be significant. In a healthy adult, insensible water loss is about 500 to 1000 mL/day. This loss increases greatly during thyroid crisis, trauma, burns, states of extreme stress, and fever. (For every

Celsius-degree increase in body temperature, insensible water loss increases by 10% to 25%.) Insensible water loss also increases when the environment is hot and dry. Patients at risk for increased insensible water loss include those being mechanically ventilated and those with rapid respirations (*tachypnea*). Insensible water loss, if not balanced by intake, can lead to severe dehydration and electrolyte imbalances.

Loss by sweating is variable and can reach a maximum rate of about 2 L/hr. Sweating is influenced by the autonomic nervous system, body temperature, and blood flow in the skin.

Water loss through stool is normally minimal. However, this loss can increase greatly with severe diarrhea or excessive fistula drainage.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

The nurse at a family picnic on a hot day in July is aware that which person is at greatest risk for dehydration while playing softball?

- A. 32-year-old male cousin who is a professional hockey player
- B. 28-year-old female cousin who has type 1 diabetes mellitus
- C. 72-year-old grandmother who is 15 pounds overweight
- D. 72-year-old grandfather who takes 81 mg of aspirin daily

HORMONAL REGULATION OF FLUID BALANCE

The endocrine system helps control fluid and electrolyte balance. Three hormones that help control these critical balances are aldosterone, antidiuretic hormone (ADH), and natriuretic peptide (NP).

Aldosterone is a hormone secreted by the adrenal cortex whenever sodium levels in the extracellular fluid (ECF) are decreased. Aldosterone prevents both water and sodium loss. When aldosterone is secreted, it acts on the kidney nephrons, triggering them to reabsorb sodium and water from the urine back into the blood. This action increases blood osmolarity and blood volume. Aldosterone prevents excessive kidney excretion of sodium. It also helps prevent blood potassium levels from becoming too high.

Antidiuretic hormone (ADH), or vasopressin, is produced in the brain and stored in the posterior pituitary gland. ADH release from the posterior pituitary gland is controlled by the hypothalamus in response to changes in blood osmolarity. The hypothalamus contains specialized cells (osmoreceptors) that are sensitive to changes in blood osmolarity. Increased blood osmolarity, especially an increase in the level of plasma sodium, results in a slight shrinkage of these cells and triggers ADH release from the posterior pituitary gland.

ADH acts directly on kidney tubules and collecting ducts, making them more permeable to water. As a result, more water is *reabsorbed* by these tubules and returned to the blood, decreasing blood osmolarity by making it more dilute. When blood osmolarity decreases, especially when the plasma sodium level is below normal, the osmoreceptors swell slightly and inhibit ADH release. Less water is then reabsorbed, and more is lost from the body in the urine. As a result, the amount of water in the extracellular fluid (ECF) decreases, bringing osmolarity up to normal.

Natriuretic peptides (NPs) are hormones secreted by special cells that line the atria of the heart (atrial natriuretic peptide

[ANP]) and the ventricles of the heart. (The peptide secreted by the heart ventricular cells is known as *brain natriuretic peptide* [BNP] because it was first discovered in the brain.) These peptides are secreted in response to increased blood volume and blood pressure, which stretch the heart tissue. NP binds to receptors in the nephrons, creating effects that are opposite of aldosterone. Kidney reabsorption of sodium is inhibited at the same time that glomerular filtration is increased, causing increased urine output. The outcome is decreased circulating blood volume and decreased blood osmolarity.

SIGNIFICANCE OF FLUID BALANCE

The Renin-Angiotensin II Pathway

The human body requires a balance of body fluids, electrolytes, and acids and bases for best function. The most important fluids to keep in balance are the blood volume (plasma volume) and the fluid inside the cells (intracellular fluid). Of these two, the most critical fluid balance to prevent death is maintaining blood volume at a sufficient level for blood pressure to remain high enough to ensure adequate perfusion and oxygenation of all organs and tissues. Balance of both water and electrolytes is needed for this very vital function.

Although having an excess of blood volume can be a problem, more conditions have the potential to lower blood volume and blood pressure to the point that tissues are not perfused well and do not receive sufficient oxygen to prevent cell death. Because low blood volume and low blood pressure can rapidly lead to death, the body has many specific actions

(mechanisms) that guard against excessive fluid loss from the plasma volume. These actions involve specific hormone levels, kidney function, and blood vessel responses to change how water and sodium are handled to maintain blood pressure.

Because the kidney is a major regulator of water and sodium balance to maintain blood pressure and perfusion to all tissues and organs, the kidneys monitor blood pressure, blood volume, blood oxygen levels, and blood osmolarity (related to sodium concentration). When the kidneys sense that any one of these parameters is getting low, they begin to secrete a substance called *renin* that sets into motion a group of hormonal and blood vessel responses to ensure that blood pressure is raised back up to normal. Fig. 13-6 summarizes these responses.

So, the triggering event is any change in the blood that indicates to the kidney that tissue and organ perfusion are at risk. Low blood pressure is a triggering event because when it gets too low, blood cannot flow through vessels into tissues and organs. Low blood volume is a triggering event because it is directly related to blood pressure. Anything that reduces blood volume (e.g., dehydration, hemorrhage) below a critical level *always* lowers blood pressure. Low blood oxygen levels also are triggering events because with too little oxygen in the blood, even if the blood reaches the tissues and organs, it cannot supply the needed oxygen and the tissues and organs could die. A low blood sodium level also is a triggering event because sodium and water are closely linked. Where sodium goes, water follows. So, anything that causes the blood to have too little sodium prevents water from staying in the blood.

FIG. 13-6 The role of the renin-angiotensin II pathway in fluid and electrolyte balance and blood pressure regulation.

The result is low blood volume with low blood pressure and poor tissue perfusion.

Once the kidneys sense that tissue and organ perfusion are at risk, special cells in the kidney tubule (in an area of the nephron known as the *juxtaglomerular complex*) begin to secrete renin into the bloodstream. Renin is an enzyme that activates some blood proteins, one of which is *angiotensinogen*. Activated angiotensinogen is *angiotensin I*, which is relatively weak and has little action. It is then acted on by another enzyme known as *angiotensin-converting enzyme* or *ACE*, which converts angiotensin I into its most active form, *angiotensin II*.

Angiotensin II starts several different activities that all work to increase blood volume and blood pressure. First, because angiotensin II is a powerful vasoconstrictor, it causes constriction of small arteries and veins throughout the body. This action increases peripheral resistance and reduces the size of the vascular bed, which raises blood pressure without adding more blood volume. At the same time, a second action of angiotensin II is that it constricts the size of the arterioles that feed the kidney nephrons. This action results in a lower glomerular filtration rate and a huge reduction of urine output. Decreasing urine output prevents further loss of water so that more is retained in the blood to help raise blood pressure. The last and slightly slower action of angiotensinogen II is to cause the adrenal glands to secrete the hormone *aldosterone*. Aldosterone is nicknamed the “water- and sodium-saving hormone” because it causes the kidneys to reabsorb water and sodium, preventing them from being excreted into the urine. This response allows more water and sodium to be returned to the blood, increasing blood pressure and blood volume. All of these actions help maintain perfusion to vital organs.

Clinical Application

The renin-angiotensin II pathway is greatly stimulated whenever the patient is in shock or is stressed to the point that the stress response is stimulated. This is why urine output is used as an indicator of perfusion adequacy after surgery or any time the patient has undergone an invasive procedure.

An additional application of this pathway is related to management of hypertension (high blood pressure). Patients who have hypertension are often asked to limit their intake of sodium. The reason for this is that a high sodium intake raises the blood level of sodium, causing more water to be retained in the blood volume and raising blood pressure. Drug therapy for hypertension management may include diuretic drugs that increase the excretion of sodium so that less is present in the blood, resulting in a lower blood volume. Another class of drugs often used to manage blood pressure is the “ACE inhibitors.” These drugs disrupt the renin-angiotensin II pathway by reducing the amount of angiotensin-converting enzyme (ACE) made so that less angiotensin II is present. With less angiotensin II, there is less vasoconstriction and reduced peripheral resistance, less aldosterone production, and greater excretion of water and sodium in the urine. All of these responses lead to decreased blood volume and blood pressure. One more class of drugs used to manage hypertension is the angiotensin receptor blockers (ARBs). These drugs disrupt the renin-angiotensin II pathway by blocking the receptors that bind with angiotensin II so that the tissues cannot respond to it and blood pressure is lowered.

FLUID IMBALANCES

All patients are at risk for some degree of fluid imbalance because many health problems can disrupt fluid intake or output. Fluid imbalances can occur in any setting.

DEHYDRATION

Pathophysiology

In **dehydration**, fluid intake or fluid retention is less than what is needed to meet the body’s fluid needs, resulting in a fluid volume deficit, especially a plasma volume deficit. It is a condition rather than a disease and can be caused by many factors (Table 13-3). Dehydration may be an *actual* decrease in total body water caused by either too little intake of fluid or too great a loss of fluid. It also can occur without an actual loss of total body water, such as when water shifts from the plasma into the interstitial space. This condition is called *relative* dehydration.

CONSIDERATIONS FOR OLDER ADULTS

Older patients are at high risk for dehydration because they have less total body water than younger adults. In addition, many older adults have decreased thirst sensation and may have difficulty with walking or other motor skills needed for obtaining fluids. They also may take drugs such as diuretics, antihypertensives, and laxatives that increase fluid excretion.

Dehydration may occur with just water loss or with water and electrolyte loss (isotonic dehydration). *Isotonic dehydration is the most common type of fluid loss problem.* Fluid is lost only from the extracellular fluid (ECF) space, including both the plasma and the interstitial spaces. There is no shift of fluids between spaces, so the intracellular fluid (ICF) volume remains normal (Fig. 13-7). Circulating blood volume is decreased (**hypovolemia**) and leads to inadequate tissue perfusion. The body’s defenses adapt (compensate) during

TABLE 13-3 COMMON CAUSES OF FLUID IMBALANCES

DEHYDRATION	FLUID OVERLOAD
• Hemorrhage • Vomiting • Diarrhea • Profuse salivation • Fistulas • Ileostomy • Profuse diaphoresis • Burns • Severe wounds • Long-term nothing-by-mouth (NPO) status • Diuretic therapy • GI suction • Hyperventilation • Renal failure (early phase) • Diabetes insipidus • Difficulty swallowing • Impaired thirst • Unconsciousness • Fever • Impaired motor function	• Excessive fluid replacement • Kidney failure (late phase) • Heart failure • Long-term corticosteroid therapy • Syndrome of inappropriate antidiuretic hormone (SIADH) • Psychiatric disorders with polydipsia • Water intoxication

FIG. 13-7 Changes in fluid compartment volumes with dehydration.

dehydration to maintain adequate blood flow to vital organs in spite of hypovolemia (Fig. 13-8).

Health Promotion and Maintenance

Mild dehydration is very common among healthy adults and is corrected or prevented easily by matching fluid intake with fluid output. Problems occur when people perform heavy exercise, especially in warm environments, without taking the time to replace excessive fluid losses. Dry climates and higher altitudes also increase fluid loss through the respiratory tract. Teach all patients to drink more fluids, especially water, whenever they engage in heavy physical activity or live in dry climates or at higher altitudes. Beverages with caffeine can increase fluid loss, as can drinks containing alcohol; thus these beverages should not be used to prevent or treat dehydration.

Moderate to severe dehydration is more likely to occur in people who are unable to obtain fluids without help. Older adults living in long-term care facilities and those adults with cognitive or motor problems depend on others for hydration. Dehydration in this population can be prevented with careful hydration programs. These programs include routinely offering residents a choice of fluids every hour or two during the

FIG. 13-8 Adaptive actions and mechanisms to preserve perfusion during dehydration.

day and at any other logical opportunity, such as when administering medications.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

History

One way of organizing history data to assess the patient's fluid status is to use Gordon's Functional Health Patterns (Gordon, 2010). The patterns that most affect fluid status are the Nutritional-Metabolic Pattern and the Elimination Pattern (Chart 13-3).

The nutritional history can reveal problems that affect fluid balance. Ask specific questions about food and liquid intake, and guide the patient in reporting accurately the amount of fluid ingested because he or she may not understand the connection between dietary intake and the onset of fluid imbalances. Also assess the types of fluids and foods ingested to determine amount and osmolarity. Many patients do not know that solid foods contain liquid. Solid foods such as ice cream, gelatin, and ices are liquids at body temperature, and these must be included when calculating fluid intake.

Collect specific information about output because exact intake and output volumes are important, as are serial daily weight measurements. If possible, weigh the patient directly rather than ask his or her weight because weight loss is an indication of dehydration. *Because 1 L of water weighs 2.2 pounds (1 kg), changes in daily weights are the best indicators of fluid losses or gains. A weight change of 1 pound corresponds to a fluid volume change of about 500 mL.*

Output includes losses not only as urine but also as sweat, diarrhea, and insensible loss during fevers. Ask specific

questions about prescribed and over-the-counter drugs, and check the dosage, the length of time taken, and the patient's adherence with the drug regimen.

Other important areas of the patient history include a sense of thirst or excessive drinking, exposure to hot environments, living at higher altitudes, and the presence of kidney or endocrine diseases. Assess the patient's level of consciousness and mental status, because changes in mental status occur with fluid imbalance. In such cases, you may need to check the accuracy of information with family members. Ask the patient about changes in ring or shoe tightness. A sudden decrease in tightness may indicate dehydration.

Older adults often use diuretics and laxatives, which can disturb fluid balance. Misuse and overuse of these drugs can lead to dehydration and electrolyte imbalances. An important issue for many older adults is that they may depend on other people to provide assistance in meeting fluid needs.

Physical Assessment/Clinical Manifestations

Nearly all body systems are affected by dehydration to some degree. The most obvious changes occur in the cardiovascular and integumentary systems.

Cardiovascular changes are good indicators of hydration status because of the relationship between plasma fluid volume and blood pressure. Heart rate increases in an attempt to maintain blood pressure with less blood volume. Peripheral pulses are weak, difficult to find, and easily blocked with light pressure. The blood pressure also decreases, as does the pulse pressure, with a greater decrease in the systolic blood pressure. Hypotension is more severe with the patient in the standing position than in the sitting or lying position (**orthostatic** or **postural hypotension**). Because the blood pressure with the patient standing may be much lower than in other positions, first measure blood pressure with the patient lying down, then sitting, and finally standing. (These measures are also called "ortho checks" or "ortho changes.") As the blood pressure decreases when changing position, the person may not have sufficient blood flow to the brain, causing the sensations of light-headedness and dizziness. This problem increases the risk for falling, especially among older adults.

Neck veins are normally distended when a patient is in the supine position, and hand veins are distended when lower than the level of the heart. Neck veins normally flatten when the patient moves to a sitting position. With dehydration, neck and hand veins are flat, even when the neck and hands are not raised above the level of the heart.

Respiratory changes include an increased rate because the decreased blood volume reduces perfusion and oxygenation. The increased respiratory rate is an attempt to maintain oxygen delivery when perfusion is decreased.

Skin changes can indicate dehydration. Assess the skin and mucous membranes for color, moisture, and turgor. In older patients, this information is less reliable because of poor skin turgor resulting from the loss of elastic tissue and increased skin dryness from the loss of tissue fluids with aging. Assess skin turgor by checking:

- How easily the skin over the back of the hand and arm can be gently pinched between the thumb and the forefinger to form a "tent"
- How soon the pinched skin resumes its normal position after release

CHART 13-3 FLUID AND ELECTROLYTE ASSESSMENT

Using Gordon's Functional Health Patterns

Nutritional-Metabolic Pattern

- What is your typical daily food intake? Describe a day's meals, snacks, and vitamins.
- How much salt do you typically add to your food? Do you use salt substitutes?
- How is your appetite?
- Do you have any difficulty chewing or swallowing?
- What is your typical daily fluid intake? What types of fluids (water, juices, soft drinks, coffee, tea, beer, other alcoholic drinks)? How much?
- Have you had any recent change in your weight? Weight gain? Weight loss? How much?
- Have you noticed a change in tightness of your rings or shoes? Tighter? Looser?

Elimination Pattern

- What is your usual bowel elimination pattern? Frequency? Character? Discomfort? Laxatives?
- What is your usual urinary elimination pattern? Frequency? Amount? Color? Odor? Control?
- Have you noticed a change in the amount of urine?
- Do you have any problem with excessive perspiration?
- Do you have any other type of drainage?

Based on Gordon, M. (2010). *Manual of nursing diagnosis* (12th ed.). Boston: Jones & Bartlett.

In generalized dehydration, skin turgor is poor, with the tent remaining for minutes after pinching the skin, and no skin depressions occur with gentle pressure. The skin is dry and scaly.

CONSIDERATIONS FOR OLDER ADULTS

Assess skin turgor in an older adult by pinching the skin over the sternum or on the forehead, rather than the back of the hand, because these areas more reliably indicate hydration (Fig. 13-9). As a person ages, the skin loses elasticity and tents on hands and arms even when the person is well hydrated.

In dehydration, oral mucous membranes are not moist. They may be covered with a thick, sticky, pastelike coating and may have cracks and fissures. The surface of the tongue may have deep furrows. This manifestation may not be accurate for assessing dehydration in patients taking drugs that have the side effect of dry mouth.

Neurologic changes with dehydration include alterations of mental status and body temperature status because blood flow in the brain is reduced. Mental status changes, especially confusion, are more common among older adults and may be the first indication of a fluid balance problem. Check to determine whether the patient is alert and oriented. [Chapter 43](#) provides more information about assessment of mental status.

The patient with dehydration often has a low-grade fever, and fever can also cause dehydration. A patient with a temperature higher than 102° F (39° C) for longer than 6 hours is especially at risk because the increased body temperature increases the rate at which fluids are lost. For every degree (Celsius) increase in body temperature above normal, a minimum of an additional 500 mL of body fluid is lost. The older adult begins to lose more body water at lower levels of fever.

Kidney changes in dehydration affect urine volume and composition. Monitor urine output, comparing total output with total fluid intake and daily weights. The urine may be concentrated, with a specific gravity greater than 1.030. The color is dark amber and has a strong odor. *Urine output below 500 mL/day for any patient without kidney disease is cause for concern. Weigh the patient each day at the same time and on the same scale.* When possible, have the patient wear the same amount and type of clothing for each weigh-in. Any weight loss over a half pound per day is fluid loss.

Laboratory Assessment

No single laboratory test result confirms or rules out dehydration. Instead, dehydration is determined by laboratory findings along with clinical manifestations (see [Table 13-1](#)).

FIG. 13-9 Examining the skin turgor of an older patient.

Usually, laboratory findings with dehydration show elevated levels of hemoglobin, hematocrit, serum osmolarity, glucose, protein, blood urea nitrogen, and various electrolytes because more water is lost and other substances remain, increasing the osmolarity or concentration of the blood (**hemoconcentration**). Hemoconcentration is not present when dehydration is caused by hemorrhage, because loss of all blood and plasma products occurs together.

INTERVENTIONS

The focus of management for the patient with dehydration is to prevent injury, prevent further fluid losses, and increase fluid compartment volumes to normal ranges. Nursing priorities include patient safety, fluid replacement, and drug therapy.

Patient safety issues and strategies are priorities of care before and during other therapies for dehydration. Monitor vital signs, especially heart rate and blood pressure. The patient with dehydration is at risk for falls because of the accompanying orthostatic hypotension, dysrhythmia, muscle weakness, and possible confusion. Assess his or her muscle strength, gait stability, and level of alertness. Instruct the patient to get up slowly from a lying or sitting position and to immediately sit down if he or she feels light-headed. Implement the falls precautions listed in [Chart 13-4](#).

Fluid replacement is key to correcting dehydration and preventing death from reduced perfusion. Best practices for nursing care of the patient with dehydration are listed in [Chart 13-5](#). Mild to moderate dehydration is corrected with oral fluid replacement if the patient is alert enough to swallow and can tolerate oral fluids. Verify that he or she does not have a health problem that requires restriction of fluid volume or fluid types. Urge fluid intake, and measure the amount ingested.

Determine whether the patient has any special fluid needs (e.g., sugar-free fluids, thickened fluids). Provide fluids the patient enjoys, and carefully time the intake schedule. Dividing by nursing shifts the total amount of fluids needed helps meet fluid needs more evenly over 24 hours with less danger

CHART 13-4 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Falls Precautions

- Assess for orthostatic hypotension.
- Assess muscle strength in legs.
- Orient the patient to the environment.
- Remind the patient to call for help before getting out of bed or a chair.
- Help the patient get out of bed or a chair.
- Provide, or remind the patient to use, a walker or cane for ambulating.
- Help the incontinent patient toilet every 1 to 2 hours.
- Clean up spills immediately.
- Provide adequate lighting at all times, especially at night.
- Keep the call light within reach, and ensure that the patient can use it.
- Place the bed in the lowest position with the brakes locked.
- Place objects that the patient needs within reach.
- Ensure that adequate handrails are present in the patient's room, bathroom, and hall.
- Encourage family members or significant other to stay with the patient.

of overload. Offer the conscious patient small volumes of fluids every hour to increase intake.

Coordinate with unlicensed assistive personnel (UAP) to meet patients' specific fluid needs. Teach UAP to offer 2 to 4 ounces of fluid every hour to patients who are dehydrated or who are at risk for dehydration. If incontinence is a concern, ensure that UAP understand that withholding fluids is not an appropriate means to prevent the problem. Instruct them to take the time to stay with patients while they drink the fluid and to note the exact amount ingested. Direct UAP to report any difficulties patients may have in swallowing or managing fluids.

Oral rehydration therapy (ORT) is a cost-effective way to replace fluids for the patient with dehydration. Specifically

CHART 13-5 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

The Patient with Dehydration

- When possible, provide oral fluids that meet the patient's dietary restrictions (e.g., sugar-free, low-sodium, thickened).
- Collaborate with other members of the health care team to determine the amount of fluids needed during a 24-hour period.
- Ensure the fluids are offered and ingested on an even schedule at least every 2 hours throughout 24 hours.
- Teach unlicensed assistive personnel to actively participate in the hydration therapy and not to withhold fluids to prevent incontinence.
- Administer prescribed IV fluids at a rate consistent with hydration needs and any known cardiac, pulmonary, or kidney problems.
- Monitor the patient's response to fluid therapy at least every 2 hours for indicators of adequate rehydration or the need for continuing therapy, especially:
 - Pulse quality
 - Urine output
 - Pulse pressure
 - Weight (every 8 hours)
- Monitor for and report indicators of fluid overload, including:
 - Bounding pulse
 - Difficulty breathing
 - Neck vein distention in the upright position
 - Presence of dependent edema
- Assess the IV and the infusion site at least hourly for indications of infiltration, extravasation, or phlebitis (e.g., swelling around the site, pain, cord-like veins, reduced drip rate).
- Administer drugs prescribed to correct the underlying cause of the dehydration (e.g., antiemetics, antidiarrheals, antibiotics, antipyretics).

formulated solutions containing glucose and electrolytes are absorbed even when the patient is vomiting or has diarrhea. These are more often used in the home setting, in long-term care, and for patients who have poor veins, making IV therapy difficult. Available ORT solutions for adults include EQUALYTE, Oralyte, and Rehydralyte.

Drug therapy for dehydration is directed at restoring fluid balance and controlling the causes of dehydration. Whenever possible, fluids are replaced orally. When dehydration is severe or life threatening or the patient cannot tolerate oral fluids, IV fluid replacement is needed. Calculation of how much fluid to replace is based on the patient's weight loss and clinical manifestations. The rate of fluid replacement depends on the degree of dehydration and the presence of other cardiac, pulmonary, or kidney problems.

The type of fluid prescribed varies with the patient's cardiovascular status and the osmolarity of the blood. [Table 13-4](#) lists the composition of common IV fluids. *The two most important areas to monitor during rehydration are pulse rate and quality and urine output.*

Drug therapy may correct some causes of the dehydration. For example, antidiarrheal drugs are prescribed when diarrhea causes dehydration. Antimicrobial therapy may be used in patients with bacterial diarrhea. Antiemetics may be used when vomiting causes dehydration. Antipyretics to reduce fever are helpful when fever makes dehydration worse.

DECISION-MAKING CHALLENGE

Patient-Centered Care; Safety

A 70-year-old man is brought to the emergency department by his wife. They were traveling together on a 700-mile car trip. She is concerned that he might have Alzheimer's disease because he suddenly does not know where he is. She tells you that her husband has only a few health problems, including high blood pressure and benign prostatic hyperplasia. He usually takes hydrochlorothiazide (Diuril) for the high blood pressure, and he did take the drug this morning as usual. She also mentions that he drank only two cups of coffee yesterday and today so that he would not need to stop so frequently to use the bathroom.

1. What risk factors does this patient have for dehydration?
2. What other information should you ask the wife?
3. How are dehydration and confusion related?
4. What assessment data should you collect and in what order? Provide a rationale for the order.
5. What are the priority safety concerns for this patient?

TABLE 13-4 CHARACTERISTICS OF COMMON INTRAVENOUS THERAPY SOLUTIONS

SOLUTION	OSMOLARITY (MOSM/L)	PH	CALORIES* (KCAL)	TONICITY
0.9% saline	308	5	0	Isotonic
0.45% saline	154	5	0	Hypotonic
5% dextrose in water (D ₅ W)	272	3.5-6.5	170	Isotonic†
10% dextrose in water (D ₁₀ W)	500	3.5-6.5	340	Hypertonic†
5% dextrose in 0.9% saline	560	3.5-6.5	170	Hypertonic†
5% dextrose in 0.45% saline	406	4	170	Hypertonic†
5% dextrose in 0.225% saline	321	4	170	Isotonic†
Ringer's lactate	273	6.5	9	Isotonic
5% dextrose in Ringer's lactate	525	4-6.5	179	Hypertonic†

Data from Trissel, L. (2009). *Handbook on injectable drugs* (15th ed.). Bethesda, MD: American Society of Hospital-System Pharmacists.

*Calories are calculated on the basis of a volume of 1000 mL.

†Solution tonicity at the time of administration. Within a short time after administration, the dextrose is metabolized and the tonicity of the infused solution decreases in proportion to the osmolality or tonicity of the non-dextrose components (electrolytes) within the water.

FLUID OVERLOAD

Pathophysiology

Fluid overload, also called *overhydration*, is an excess of body fluid. It is not a disease but, rather, a clinical sign of a problem in which fluid intake or retention is greater than the body's fluid needs. Fluid overload may be either an actual excess of total body fluid or a relative fluid excess. The most common type of fluid overload is hypervolemia (Fig. 13-10) because the problems result from excessive fluid in the extracellular fluid (ECF) space. Most problems caused by fluid overload are related to excessive fluid in the vascular space or to dilution of specific electrolytes and blood components. The conditions leading to fluid overload are related to excessive intake or inadequate excretion of fluid. See Table 13-3 for causes of

fluid overload. Fig. 13-11 outlines the adaptive changes the body makes in response to mild or moderate fluid overload. When overload is severe or occurs in a person with poor cardiac or kidney function, it can lead to heart failure and pulmonary edema.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Patients with fluid overload often have pitting edema (Fig. 13-12). Other manifestations are usually seen in the

FIG. 13-10 Changes in fluid compartment volumes with fluid overload.

FIG. 13-12 Pitting edema of the left foot and ankle.

FIG. 13-11 Adaptive actions and mechanisms to prevent cardiac and pulmonary complications during fluid overload. (ADH, Antidiuretic hormone; ECF, extracellular fluid.)

cardiovascular, respiratory, neuromuscular, integumentary, and GI systems (Chart 13-6).

Fluid overload is diagnosed based on assessment findings and the results of laboratory tests. Usually, serum electrolyte values are normal, but decreased hemoglobin, hematocrit, and serum protein levels may result from excessive water in the vascular space (**hemodilution**).

INTERVENTIONS

The focus of priority nursing interventions for patients with fluid overload is to ensure patient safety, restore normal fluid balance, provide supportive care until the imbalance is resolved, and prevent future fluid overload. Drug therapy, nutrition therapy, and monitoring are the basis of intervention.

Patient safety is the first priority. Interventions are implemented to prevent fluid overload from becoming worse, leading to pulmonary edema and heart failure. Any patient with fluid overload, regardless of age, is at risk for these complications. Older adults or those with cardiac problems, kidney problems, pulmonary problems, or liver problems are at greater risk.

Monitor for indicators of increased fluid overload (bounding pulse, increasing neck vein distention, presence of crackles in lungs, increasing peripheral edema, reduced urine output) at least every 2 hours.

! NURSING SAFETY PRIORITY

Critical Rescue

Pulmonary edema can occur very quickly and can lead to death. Notify the health care provider of any change that indicates the fluid overload either is not responding to therapy or is becoming worse.

The patient with fluid overload and edema is at risk for skin breakdown. Use a pressure-reducing or

pressure-relieving overlay on the mattress. Assess skin pressure areas daily for signs of redness or open area, especially the coccyx, elbows, hips, and heels. Because many patients with fluid overload may be receiving oxygen by mask or nasal cannula, check the skin integrity around the mask, nares, and ears and under the elastic band. Help the patient change positions every 2 hours, or ensure that unlicensed assistive personnel (UAP) perform this action.

Drug therapy focuses on removing the excess fluid. Diuretics are prescribed for fluid overload if kidney failure is not the cause. These drugs increase kidney water or sodium excretion. High-ceiling (loop) diuretics, such as furosemide (Lasix, Furoside ) , may be prescribed. (See Chapter 38 for discussion of diuretic therapy.) If there is concern that too much sodium and other electrolytes would be lost using loop diuretics or if the patient has syndrome of inappropriate antidiuretic hormone (SIADH), conivaptan (Vaprisol) or tolvaptan (Samsca) may be prescribed.

Monitor the patient for response to drug therapy, especially weight loss and increased urine output. Observe for manifestations of electrolyte imbalance, especially changes in electrocardiogram (ECG) patterns. Assess laboratory findings, especially sodium and potassium values, every 8 hours or whenever they are drawn.

Nutrition therapy for the patient with *chronic* fluid overload may involve restrictions of both fluid and sodium intake to control fluid volume. Review the patient's serum sodium levels whenever fluid overload is present. Often sodium restriction involves only "no added salt" to ordinary table foods when fluid overload is mild. For more severe fluid overload, the patient may be restricted to 2 g/day to 4 g/day of sodium. When sodium restriction is ongoing, teach the patient and family how to check food labels for sodium content and how to keep a daily record of sodium ingested. Explain to the patient and family the reason for any fluid restriction and the importance of adhering to the prescribed restriction.

Monitoring intake and output and weight provides information on therapy effectiveness. Teach UAP that these measurements need to be accurate, not just estimated, because treatment decisions are based on these findings. In addition to regulating the total amount of fluid ingested in a 24-hour period, schedule fluid offerings throughout the 24 hours. Teach UAP to check urine for color and character and to report these findings. Check the urine specific gravity (a specific gravity below 1.005 may indicate fluid overload). If the patient is receiving IV therapy, infuse the exact amount prescribed.

Fluid retention may not be visible. Remember that rapid weight gain is the best indicator of fluid retention and overload. Metabolism can account for no more than a half pound of weight gain in one day. Each pound of weight gained (after the first half pound) equates to 500 mL of retained water. Weigh the patient at the same time every day (before breakfast), using the same scale. Whenever possible, have the patient wear the same type of clothing for each weigh-in.

If the patient is discharged to home before the fluid overload has completely resolved or has continuing risk for fluid overload, teach him or her and the family to monitor weight at home. Suggest that a record of these daily weights be kept to show the health care provider at checkups. Also, instruct

CHART 13-6 KEY FEATURES

Fluid Overload

Cardiovascular Changes

- Increased pulse rate
- Bounding pulse quality
- Full peripheral pulses
- Elevated blood pressure
- Decreased pulse pressure
- Elevated central venous pressure
- Distended neck and hand veins
- Engorged varicose veins
- Weight gain

Respiratory Changes

- Increased respiratory rate
- Shallow respirations
- Increased dyspnea with exertion or in the supine position
- Moist crackles present on auscultation

Skin and Mucous Membrane Changes

- Pitting edema in dependent areas
- Skin pale and cool to touch

Neuromuscular Changes

- Altered level of consciousness
- Headache
- Visual disturbances
- Skeletal muscle weakness
- Paresthesias

Gastrointestinal Changes

- Increased motility
- Enlarged liver

the patient to call his or her health care provider for more than a 3-pound gain in a week or more than a 1- to 2-pound gain in 24 hours.

NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

The client who has fluid overload has been taking a diuretic for the past 2 days and now experiences these changes. Which change indicates to the nurse that the diuretic is effective?

- A. Weight loss of 7 pounds
- B. Heart rate increased from 72 to 80
- C. Respiratory rate decreased from 20 to 16
- D. Morning blood glucose decreased from 142 mg/dL to 110 mg/dL

ELECTROLYTE BALANCE AND IMBALANCES

Electrolytes, or **ions**, are substances in body fluids that carry an electrical charge. **Cations** have positive charges; **anions** have negative charges. Body fluids are electrochemically neutral, which means that the number of positive ions is balanced by an equal number of negative ions. However, the distribution of ions differs in the extracellular fluid (ECF) and the intracellular fluid (ICF) (Fig. 13-13).

Most electrolytes have different concentrations in the ICF and ECF. This concentration difference helps maintain membrane excitability and allows nerve impulse transmission. The normal ranges of electrolyte concentration are very narrow. So, even small changes in these levels can cause major problems.

Electrolyte imbalances can occur in healthy people as a result of changes in fluid intake and output. These imbalances are usually mild and are easily corrected. Severe electrolyte imbalances with actual losses or retention of specific electrolytes are life threatening and can occur in any setting. People at greatest risk for severe imbalances are older patients, patients with chronic kidney or endocrine disorders, patients who are mentally impaired, and patients who are taking drugs that alter fluid and electrolyte

levels. *All ill people are at some risk for electrolyte imbalances.*

Table 13-1 lists major electrolytes, their normal serum levels, and the significance of abnormal values. Most electrolytes enter the body in ingested food. The normal concentration of blood electrolytes changes slightly with the aging process. Chart 13-1 lists the normal electrolyte values for people older than 60 years.

Electrolyte homeostasis is controlled by balancing the dietary intake of electrolytes with the kidney excretion or reabsorption of electrolytes. For example, the plasma level of potassium is maintained between 3.5 and 5.0 mEq/L (mmol/L). The high potassium level in common foods such as meat and citrus fruit could increase the ECF potassium level and lead to major problems. Normally this does not occur because kidney excretion of potassium keeps pace with potassium intake and prevents major changes in the blood potassium level.

CONSIDERATIONS FOR OLDER ADULTS

Older adults are at risk for most electrolyte imbalances as a result of age-related organ changes, especially a reduction of kidney function. Older adults have less total body water than younger adults and therefore are more at risk for fluid imbalances. They are more likely to be taking drugs that affect fluid or electrolyte balance.

SODIUM

Sodium (Na^+), a mineral, is the major *cation* (positively charged particle) in the extracellular fluid (ECF) and maintains ECF osmolarity. Sodium levels of the ECF are high (136 to 145 mEq/L), and the intracellular fluid (ICF) sodium levels are low (about 14 mEq/L). Keeping this difference in sodium levels is vital for skeletal muscle contraction, cardiac contraction, nerve impulse transmission, and normal osmolarity and volume of the ECF. Sodium levels and movement influence water balance because “where sodium goes, water follows.” The ECF sodium level determines whether water is retained, excreted, or moved from one fluid space to another.

Plasma volume	Interstitial fluid	Intracellular fluid
Volume 3.5-5.5 L Osmolarity 270-300 mOsm Sodium 136-145 mEq/L Potassium 3.5-5.0 mEq/L Chloride 96-109 mEq/L Calcium 9.0-10.5 mg/dL Magnesium 1.3-2.1 mEq/L Protein 7-8 g/L	Volume ~10 L Osmolarity 270-300 mOsm Sodium 135-145 mEq/L Potassium 3.5-5.0 mEq/L Chloride ~118 mEq/L Calcium 7.0-9.0 mg/dL Magnesium ~1.3 mEq/L Protein ~2 g/L	Volume 25-30 L Osmolarity 270-300 mOsm Sodium 14 mEq/L Potassium 140 mEq/L Chloride ~4-6 mEq/L Calcium 1.0-8.0 mg/dL Magnesium 6-30 mEq/L Protein 16 g/L

FIG. 13-13 The electrolyte composition of various body fluids.

To maintain electrical balance, the sodium (a cation) level within a body fluid must be matched by an equal number of anions (negatively charged substances). Each positive charge in the ECF is balanced by a negative charge so the fluid does not carry either an overall positive or an overall negative charge. When this balance is present, the fluid is electrically neutral. Changes in plasma sodium levels seriously change fluid volume and the distribution of other electrolytes.

Sodium enters the body through the ingestion of many foods and fluids. Foods with the highest sodium levels are those that are processed or preserved, such as smoked or pickled foods. Snack foods are often very high in sodium. Condiments, such as salt, soy sauce, and relishes, are also high in sodium. Foods lowest in sodium include fresh fish and poultry and most fresh vegetables and fruit. The average dietary intake of sodium among North Americans is about 6 to 13 g/day. Sodium is also stored within the kidney tissues and is released to the ECF as needed.

Despite variation in sodium intake from one day to the next, the blood sodium level usually remains within the normal range. Serum sodium balance is regulated by the kidney under the influences of aldosterone, antidiuretic hormone (ADH), and natriuretic peptide (NP), as described on pp. 171-172.

Low serum sodium levels inhibit the secretion of ADH and NP and trigger aldosterone secretion. Together these actions increase serum sodium levels by increasing kidney reabsorption of sodium and enhancing kidney loss of water.

High serum sodium levels inhibit aldosterone secretion and directly stimulate secretion of ADH and NP. Together these hormones increase kidney excretion of sodium and kidney reabsorption of water.

HYPONATREMIA

Pathophysiology

Hyponatremia is a serum sodium (Na^+) level below 136 mEq/L (mmol/L). Sodium imbalances often occur with fluid volume imbalances because the same hormones regulate both sodium and water balance. The problems caused by hyponatremia involve two mechanisms—reduced excitable membrane depolarization and cellular swelling.

Excitable cell membrane depolarization depends on high extracellular fluid (ECF) levels of sodium being available to cross cell membranes and move into cells in response to a stimulus. Hyponatremia makes depolarization slower so that excitable membranes are less excitable.

With hyponatremia, the osmolarity of the ECF is lower than that of the intracellular fluid (ICF). As a result, water moves into the cell, causing swelling. Even a small amount of swelling can reduce cell function. Larger amounts of swelling can make the cell burst and die (*lysis*).

Many conditions and drugs can lead to hyponatremia (Table 13-5). One of the most common causes of low sodium levels is the prolonged use and overuse of diuretics, especially in older adults or in anyone who is also restricting sodium intake. When these drugs are used to manage fluid overload, sodium is lost along with the extra water. Hyponatremia can result from the loss of total body sodium, the movement of sodium from the blood to other fluid spaces, or the dilution of serum sodium from excessive water in the plasma.

TABLE 13-5 COMMON CAUSES OF HYPONATREMIA

Actual Sodium Deficits

- Excessive diaphoresis
- Diuretics (high-ceiling diuretics)
- Wound drainage (especially gastrointestinal)
- Decreased secretion of aldosterone
- Hyperlipidemia
- Kidney disease (scarred distal convoluted tubule)
- Nothing by mouth
- Low-salt diet
- Cerebral salt-wasting syndrome
- Hyperglycemia

Relative Sodium Deficits (Dilution)

- Excessive ingestion of hypotonic fluids
- Psychogenic polydipsia
- Freshwater submersion accident
- Kidney failure (nephrotic syndrome)
- Irrigation with hypotonic fluids
- Syndrome of inappropriate antidiuretic hormone secretion
- Heart failure

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

The manifestations of hyponatremia are caused by its effects on excitable cellular activity. The cells especially affected are those involved in cerebral, neuromuscular, intestinal smooth muscle, and cardiovascular functions.

Cerebral changes are the most obvious problems of hyponatremia. First establishing the patient's usual cognitive and behavioral patterns is essential because either depressed activity or excessive activity (and sometimes both) may occur. Behavioral changes result from cerebral edema and increased intracranial pressure. Closely observe and document the patient's behavior, level of consciousness, and mental status. A sudden onset of acute confusion or increased confusion is often seen in older adults who have low serum sodium levels.

Neuromuscular changes are seen as general muscle weakness. Assess the patient's neuromuscular status during each nursing shift for changes from baseline. Deep tendon reflexes diminish, and muscle weakness is worse in the legs and arms. Assess muscle strength in several ways, including arm muscle strength and leg muscle strength. Test arm muscle strength first by having the patient squeeze your hand. Another way to test arm muscle strength is to have the patient flex his or her arms against the chest and keep them flexed while you attempt to pull them away from the chest. Test leg muscle strength by having the patient push both feet against a flat surface (like a box or a board) while you apply resistance to the opposite side of the flat surface.

! NURSING SAFETY PRIORITY

Action Alert

If muscle weakness is present, immediately check respiratory effectiveness because ventilation depends on adequate strength of respiratory muscles.

Intestinal changes include increased motility, causing nausea, diarrhea, and abdominal cramping. Assess the GI system by listening to bowel sounds and observing stools. Bowel sounds are hyperactive, with rushes and gurgles over the splenic flexure and in the lower left quadrant. Bowel movements are frequent and watery.

Cardiovascular changes are seen as changes in cardiac output. The cardiac responses to hyponatremia with **hypovolemia** (decreased plasma volume) include a rapid, weak, thready pulse. Peripheral pulses are difficult to palpate and are easily blocked with light pressure. Blood pressure is decreased, and the patient may have severe hypotension when moving from a lying or sitting position to a standing position (orthostatic hypotension), leading to light-headedness or dizziness. The central venous pressure is low.

When hyponatremia occurs with **hypervolemia** (fluid overload), cardiac changes include a full or bounding pulse with normal or high blood pressure. Peripheral pulses are full and difficult to block; however, they may not be palpable if edema is present.

INTERVENTIONS

The health care provider determines the specific cause of the low sodium level to plan the most appropriate medical treatment. Interventions with drug therapy and nutrition therapy are used to restore serum sodium levels to normal and prevent complications from fluid overload or a too-rapid change in serum sodium level. *The priorities for nursing care of the patient with hyponatremia are monitoring the patient's response to therapy and preventing hypernatremia and fluid overload.*

Drug therapy first involves reducing the doses of any drugs that increase sodium loss, such as loop diuretics and thiazide diuretics. Other regimens vary depending on whether fluid imbalance occurs with hyponatremia. When hyponatremia occurs with a fluid deficit, IV saline infusions are prescribed to restore both sodium and fluid volume. Severe hyponatremia may be treated with small-volume infusions of hypertonic (2%-3%) saline. These infusions are delivered using a controller to prevent accidental increases in infusion rate. Monitor the infusion rate and the patient's response.

When hyponatremia occurs with fluid excess, drug therapy includes giving drugs that promote the excretion of water rather than sodium, such as conivaptan (Vaprisol) or tolvaptan (Samsca). Drug therapy for hyponatremia caused by inappropriate secretion of antidiuretic hormone (ADH) may also include agents that antagonize ADH, such as lithium and demeclocycline (Declomycin). Assess hourly for signs of excessive fluid loss, potassium loss, and increased sodium levels.

Nutrition therapy can help restore normal sodium balance in mild hyponatremia. Collaborate with the registered dietitian (RD) to teach the patient about which foods to increase in the diet. Therapy involves increasing oral sodium intake and restricting oral fluid intake. Fluid restriction may be needed long-term when fluid overload is the cause of the hyponatremia or when kidney fluid excretion is impaired. Nursing actions for patient safety, skin protection, measurement of fluid intake and output, and patient and family teaching are the same as those for fluid overload on pp. 179-180.

TABLE 13-6 COMMON CAUSES OF HYPERNATREMIA

Actual Sodium Excesses	Relative Sodium Excesses
• Hyperaldosteronism • Kidney failure • Corticosteroids • Cushing's syndrome or disease • Excessive oral sodium ingestion • Excessive administration of sodium-containing IV fluids	• Nothing by mouth • Increased rate of metabolism • Fever • Hyperventilation • Infection • Excessive diaphoresis • Watery diarrhea • Dehydration

NCLEX EXAMINATION CHALLENGE

Psychosocial Integrity

The family of a client with chronic hyponatremia asks if the water restriction is a punishment for his uncooperative behavior. What is the nurse's best response?

- "No, limiting fluid intake decreases the risk for kidney failure."
- "No, limiting water intake prevents him from losing too much fluid by vomiting."
- "No, limiting fluid intake keeps his blood from becoming more dilute and causing other complications."
- "No, limiting fluid decreases his sense of thirst and prevents him from drinking liquids that contain an excess of sodium."

HYPERNATREMIA

Pathophysiology

Hypernatremia is a serum sodium level over 145 mEq/L (mmol/L). High serum sodium levels can be caused by or can cause changes in fluid volumes. Table 13-6 lists common causes of hypernatremia.

As serum sodium level rises, a larger difference in sodium levels occurs between the extracellular fluid (ECF) and the intracellular fluid (ICF). More sodium is present to move rapidly across cell membranes during depolarization, making excitable tissues more easily excited. This condition is called **irritability**, and excitable tissues over-respond to stimuli. In addition, water moves from the cells into the ECF to dilute the hyperosmolar ECF. So, when serum sodium levels are high, severe cellular dehydration occurs. Eventually the dehydrated excitable tissues may no longer be able to respond to stimuli.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

The manifestations of hypernatremia vary with the severity of sodium imbalance and whether a fluid imbalance is also present. Changes are first seen in excitable membrane activity, especially nerve, skeletal muscle, and cardiac function.

Nervous system changes start with altered cerebral function. Assess the patient's mental status for attention span, recall of recent events, and cognitive function. In hypernatremia with normal or decreased fluid volumes, the patient may have a short attention span and be agitated or confused about recent events. Manic episodes or seizures may occur if serum

sodium continues to rise. When hypernatremia occurs with fluid overload, the patient may be lethargic, drowsy, stuporous, and even comatose.

Skeletal muscle changes vary with the degree of sodium increases. Mild rises cause muscle twitching and irregular muscle contractions. As hypernatremia worsens, the muscles and nerves are less able to respond to a stimulus and muscles become progressively weaker. Late, the deep tendon reflexes are reduced or absent. Muscle weakness occurs bilaterally and has no specific pattern. Observe for twitching in muscle groups. Assess muscle strength by having the patient perform handgrip and arm flexion against resistance as described on p. 181. The advanced practice nurse may check reflexes by lightly tapping the patellar (knee) tendons and Achilles (heel) tendons with a reflex hammer and measuring the movement.

Cardiovascular changes include decreased contractility because high sodium levels slow the movement of calcium into the heart cells. Measure blood pressure and the rate and quality of the apical and peripheral pulses. Pulse rate and blood pressure may be normal, above normal, or below normal, depending on the fluid volume and how rapidly the imbalance occurred.

Pulse rate is increased in patients with hypernatremia and hypovolemia. Peripheral pulses are difficult to palpate and are easily blocked. Hypotension and severe orthostatic (postural) hypotension are present, and pulse pressure is reduced.

Patients with hypernatremia and hypervolemia have slow to normal bounding pulses. Peripheral pulses are full and difficult to block. Neck veins are distended, even with the patient in the upright position. Blood pressure, especially diastolic blood pressure, is increased.

INTERVENTIONS

Drug and nutrition therapies are used to prevent further increases in serum sodium and decrease high serum sodium levels. Other medical interventions used when sodium levels become life threatening include hemodialysis and blood ultrafiltration. *Priorities for nursing care of the patient with hypernatremia include monitoring his or her response to therapy and ensuring patient safety by preventing hyponatremia and dehydration.*

Drug therapy is used to restore fluid balance when hypernatremia is caused by fluid loss. Hypotonic IV infusions, usually 0.225% sodium chloride, are prescribed. Hypernatremia caused by fluid and sodium losses (in which sodium losses are less than fluid losses) may require fluid replacement with IV infusions of solutions that are still hypotonic but contain slightly higher concentrations of sodium (e.g., 0.45% sodium chloride). Hypernatremia caused by poor kidney excretion of sodium requires drug therapy with diuretics that promote sodium loss, such as furosemide (Lasix, Furoside ) or bumetanide (Bumex). Assess the patient hourly for symptoms of excessive losses of fluid, sodium, or potassium.

Nutrition therapy can prevent or correct mild hypernatremia by ensuring adequate water intake, especially among older adults or those who may not have self-access to water. Dietary sodium restriction may be needed to prevent sodium excess when kidney problems are present. In addition, fluids must often be restricted. Collaborate with the dietitian to teach the patient how to determine the sodium content of

foods, beverages, and drugs. Nursing actions for patient safety, skin protection, measurement of fluid intake and output, and patient and family teaching are similar to those for fluid overload on pp. 179-180.

POTASSIUM

Potassium (K^+) is the major cation of the intracellular fluid (ICF). The normal plasma potassium level ranges from 3.5 to 5.0 mEq/L (mmol/L) (see Table 13-1). The normal ICF potassium level is about 140 mEq/L (mmol/L). Because of its high levels inside cells, potassium has some control over intracellular osmolarity and volume. Keeping this large difference in potassium concentration between the ICF and the extracellular fluid (ECF) is critical for excitable tissues to depolarize and generate action potentials. Other functions of potassium include regulating protein synthesis and regulating glucose use and storage.

Because potassium levels in the blood and interstitial fluid are so low, any change seriously affects physiologic activities. For example, a decrease in blood potassium of only 1 mEq/L (from 4 mEq/L to 3 mEq/L) is a 25% difference in total ECF potassium concentration. In contrast, a 1 mEq/L decrease in blood sodium level (from 130 mEq/L to 129 mEq/L) is, overall, a much smaller change (less than 1%) in total ECF sodium concentration.

Almost all foods contain potassium. It is highest in meat, fish, and many (but not all) vegetables and fruits. It is lowest in eggs, bread, and cereal grains. Typical potassium intake is about 2 to 20 g/day. Despite heavy potassium intake, the healthy adult keeps plasma potassium levels within the narrow range of normal values needed for physiologic function.

The main controller of ECF potassium level is the sodium-potassium pump within the membranes of all body cells. This pump moves extra sodium ions from the ICF and moves extra potassium ions from the ECF back into the cell. In this way, the serum potassium level remains low and the cellular potassium remains high. At the same time, this action also helps the serum sodium level remain high and the cellular sodium level remain low.

Potassium control also occurs through kidney function, because about 80% of potassium removed from the body occurs by the kidney. Kidney excretion of potassium is enhanced by aldosterone. No hormone has been identified that enhances kidney reabsorption of potassium.

HYPOKALEMIA

Pathophysiology

Because 98% of total body potassium (K^+) is inside cells, minor changes in extracellular potassium levels cause major changes in cell membrane excitability and in other cellular processes. **Hypokalemia** is a serum potassium level below 3.5 mEq/L (mmol/L). *It can be life threatening because every body system is affected.*

Low serum potassium levels increase the difference in the amount of potassium between the fluid inside the cells (ICF) and the fluid outside the cells (ECF). This increased difference reduces the excitability of cells. As a result, the cell membranes of all excitable tissues, such as nerve and muscle, are less responsive to normal stimuli.

TABLE 13-7 COMMON CAUSES OF HYPOKALEMIA

Actual Potassium Deficits

- Inappropriate or excessive use of drugs:
 - Diuretics
 - Digitalis
 - Corticosteroids
- Increased secretion of aldosterone
- Cushing's syndrome
- Diarrhea
- Vomiting
- Wound drainage (especially gastrointestinal)
- Prolonged nasogastric suction
- Heat-induced excessive diaphoresis
- Kidney disease impairing reabsorption of potassium
- Nothing by mouth

Relative Potassium Deficits

- Alkalosis
- Hyperinsulinism
- Hyperalimentation
- Total parenteral nutrition
- Water intoxication
- IV therapy with potassium-poor solutions

When the loss of ECF potassium is gradual, cells adjust and cellular potassium decreases in proportion to the ECF potassium level. The potassium difference between the two fluid spaces remains unchanged, and symptoms of hypokalemia may not appear until the potassium loss is extreme. Rapid reduction of serum potassium levels causes dramatic changes in function.

Hypokalemia may result either from an *actual* total body potassium loss or from the movement of potassium from the ECF to the ICF, causing a *relative* decrease in extracellular potassium level. Table 13-7 lists the common causes of hypokalemia.

Actual potassium depletion occurs when potassium loss is excessive or when potassium intake is not adequate to match normal potassium loss. Relative hypokalemia occurs when total body potassium levels are normal but the potassium distribution between fluid spaces is abnormal, or it is diluted by excess water.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Age is important because the kidneys' ability to concentrate urine decreases with aging, which increases potassium loss. Older adults are more likely to use drugs that lead to potassium loss.

Drugs, especially diuretics, corticosteroids, and beta-adrenergic agonists or antagonists, can increase potassium loss through the kidneys. Ask about prescription and over-the-counter drug use. A common cause of hypokalemia is the prolonged use and misuse of diuretics. In patients taking digoxin (Lanoxin, Novodigoxin ) , hypokalemia increases the sensitivity of the cardiac muscle to the drug and may result in digoxin toxicity, even when the digoxin level is within the therapeutic range. Ask whether the patient takes a

potassium supplement, such as potassium chloride (KCl), or eats foods that have high concentrations of potassium, such as bananas, citrus fruits or juices, raisins, and meat. The patient may not be taking the supplement as prescribed because of its unpleasant taste.

Disease can lead to potassium loss. Ask the patient about chronic disorders, as well as recent illnesses and medical or surgical interventions. A thorough nutrition history, including a typical day's food and beverage intake, helps identify patients at risk for hypokalemia.

Respiratory changes are likely because of weakness of the muscles needed for breathing. Skeletal muscle weakness results in shallow respirations. *Thus respiratory status should be assessed first in any patient who might have hypokalemia.* Assess the patient's breath sounds, ease of respiratory effort, color of nail beds and mucous membranes, and rate and depth of respiration. Assess respiratory status at least every 2 hours because respiratory insufficiency is a major cause of death.

Musculoskeletal changes include skeletal muscle weakness in response to hypokalemia. A stronger stimulus is needed to begin muscle contraction. A patient may be so weak that he or she cannot stand. Hand grasps are weak, and a decreased response to deep tendon reflex stimulation (**hyporeflexia**) may be seen. Severe hypokalemia causes flaccid paralysis. Assess for muscle weakness, and determine the patient's ability to perform ADLs.

Cardiovascular changes are assessed by first palpating the peripheral pulses. In the patient with hypokalemia, the pulse is usually thready and weak. Palpation is difficult, and the pulse is easily blocked with light pressure. The pulse rate can range from very slow to very rapid, and an irregular heartbeat (dysrhythmia) may be present. Measure blood pressure with the patient in the lying, sitting, and standing positions, because orthostatic (postural) hypotension occurs with hypokalemia.

Neurologic changes from hypokalemia include altered mental status. The patient may have short-term irritability and anxiety followed by lethargy that progresses to acute confusion and coma as hypokalemia worsens.

Behavioral changes caused by hypokalemia can occur quickly. If needed, obtain information about the patient's behavior from close family members or friends if the patient is confused. The patient may be lethargic and unable to perform simple problem-solving tasks such as counting by threes. As hypokalemia progresses, the patient may become more confused, especially to time and place. In severe hypokalemia, coma may develop.

Intestinal changes occur with hypokalemia because smooth muscle contractions in the intestinal tract are decreased, which leads to decreased peristalsis. The patient has hypoactive bowel sounds and may have nausea, vomiting, constipation, and abdominal distention. Assess distention by measuring abdominal girth. Auscultate for bowel sounds in all four abdominal quadrants to assess the extent of decreased peristalsis. *Severe hypokalemia can cause the absence of peristalsis (paralytic ileus).*

Laboratory data confirm hypokalemia (serum potassium value below 3.5 mEq/L [mmol/L]). Hypokalemia causes ECG changes in the heart, including ST-segment depression, flat or inverted T waves, and increased U waves. *Dysrhythmias can lead to death, particularly in older adults who are taking digoxin.*

DECISION-MAKING CHALLENGE

Patient-Centered Care; Safety

The patient is a 75-year-old woman who is admitted to the hospital with a diagnosis of possible paralytic ileus. She has no bowel sounds, and her abdomen is distended. She says her last bowel movement was 1 week ago. Her other health problems include mild congestive heart failure and hypertension. Her daily medications include:

Digoxin (Lanoxin) 0.125 mg orally

Furosemide (Lasix) 80 mg orally

Potassium (Klor-KonM20) 20 mEq (1 tablet) orally twice daily

When you ask her about her medications, she tells you that she takes her digoxin daily at 8 AM, as prescribed, but that she sometimes takes twice as much Lasix as prescribed and no longer takes the potassium because it bothers her stomach. She says, "I don't need the potassium because I always eat apples or grapefruit every day." Her vital signs are:

T = 98° F; P = 110, thready, slightly irregular; R = 30, shallow;
BP = 90/60; SPO₂ = 95%

1. What other assessment data should you obtain?
2. How can her drug therapy influence her intestinal tract?
3. Is this patient's dietary intake of potassium sufficient for potassium replacement? Why or why not?
4. Is she at risk for any other fluid or electrolyte imbalances? If so, which ones and why?
5. Should oxygen be applied? Why or why not?
6. Should she be monitored by ECG? Why or why not?
7. What are the priority safety concerns for this patient?

INTERVENTIONS

Interventions for hypokalemia aim to prevent potassium loss, increase serum potassium levels, and ensure patient safety. Drug and nutrition therapies help restore normal serum potassium levels. *The priorities for nursing care of the patient with hypokalemia are (1) ensuring adequate oxygenation, patient safety for falls prevention, and prevention of injury from potassium administration and (2) monitoring the patient's response to therapy.* Chart 13-7 highlights best practice activities when caring for a patient with hypokalemia.

Drug therapy for the treatment and prevention of hypokalemia includes additional potassium and drugs to prevent potassium loss. Most potassium supplements are potassium chloride, potassium gluconate, or potassium citrate. The amount and the route of potassium replacement depend on the degree of loss.

Potassium is given IV for severe hypokalemia. The drug is available in different concentrations, and this drug carries a high alert warning as a concentrated electrolyte solution. The Joint Commission has mandated that concentrated potassium be diluted and added to IV solutions only in the pharmacy by a registered pharmacist and that vials of concentrated potassium not be available in patient care areas. *Before infusing any IV solution containing potassium chloride (KCl), check and re-check the dilution of the drug in the IV solution container.*

NURSING SAFETY PRIORITY

Drug Alert

A dilution no greater than 1 mEq of potassium to 10 mL of solution is recommended for IV administration. The maximum recommended infusion rate is 5 to 10 mEq/hr; this rate is never to exceed 20 mEq/hr under any circumstances. Older patients may not be able to handle this rate. In accordance with the National Patient Safety Goals (NPSGs), potassium is not given by IV push to avoid causing cardiac arrest.

CHART 13-7 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

The Patient with Hypokalemia

- Question the continued use of drugs that increase excretion of potassium (e.g., thiazide and loop diuretics).
- Administer prescribed oral potassium supplement, well diluted and with a meal or just after a meal or snack to prevent nausea and vomiting.
- Prevent accidental overdose of IV potassium by checking and re-checking the concentration of potassium in the IV solution, ensuring that the maximum concentration is no greater than 1 mEq/10 mL of solution.
- Establish an IV access in a large vein with a high volume of flow, avoiding the hand.
- Assess the IV access for placement and an adequate blood return *before* administering potassium-containing solutions.
- Use a controller for solution delivery, maintaining an infusion rate not faster than 5 to 10 mEq of potassium per hour.
- Assess the IV site hourly.
- Stop the infusion immediately if the patient reports pain or burning or if any manifestation of infiltration occurs.
- If possible, monitor electrocardiography (ECG) continuously.
- Monitor patient responses every 1 to 2 hours to determine therapy effectiveness and the potential for hyperkalemia.
 - Indications of therapy effectiveness:
 - Respiratory rate is greater than 12 breaths per minute
 - Oxygen saturation is at least 95% (or has returned to the patient's normal baseline)
 - The patient can cough effectively
 - Hand grasp strength increases
 - Deep tendon reflexes are present
 - Bowel sounds are present and active
 - Pulse is easily palpated and regular
 - Systolic blood pressure when standing remains within 20 mm Hg of the systolic pressure obtained when the patient is sitting or lying down
 - ST segment returns to the isoelectric line
 - T waves increase in size and are positive
 - U waves decrease or disappear
 - Patient's cognition resembles his or her prehypokalemic state
 - Serum potassium level is between 3.5 and 5.0 mEq/L
 - Indications of hyperkalemia:
 - Heart rate is less than 60 beats per minute
 - P waves are absent
 - T waves are tall
 - PR intervals are prolonged
 - QRS complexes are wide
 - Deep tendon reflexes are hyperactive
 - Bowel sounds are hyperactive
 - Numbness or tingling is present in the hands and feet and around the mouth
 - The patient is anxious
 - Serum potassium level is above 5.0 mEq/L
- Keep patient on bedrest until hypokalemia resolves, or provide assistance when out of bed to prevent falls.

Potassium is a severe tissue irritant and is never given by IM or subcutaneous injection. Tissues damaged by potassium can become necrotic and slough, causing loss of function and requiring reconstructive surgery. IV potassium solutions irritate veins and can cause phlebitis. Check the prescription carefully to ensure that the patient receives the correct amount of potassium. Assess the IV site hourly, and ask the patient whether he or she feels burning or pain at the site.

Oral potassium preparations may be taken as liquids or solids. Potassium has a strong, unpleasant taste that is difficult to mask, although it can be mixed with many liquids.

! NURSING SAFETY PRIORITY**Action Alert**

If infiltration of an IV solution containing potassium occurs, stop the IV solution immediately, remove the venous access, and notify the health care provider or Rapid Response Team. Document these actions along with a complete description of the IV site.

Some preparations are already flavored. Because potassium chloride can cause nausea and vomiting, give the drug during or after a meal and advise patients using the drug at home not to take it on an empty stomach.

Diuretics that increase the kidney excretion of potassium can cause hypokalemia. These classes of diuretics include high-ceiling (loop) diuretics (e.g., furosemide [Lasix, Furoside ♣] and bumetanide [Bumex]) and the thiazide diuretics. Avoid these drugs in patients with hypokalemia. A potassium-sparing diuretic may be prescribed for patients with hypokalemia who need diuretic therapy. Potassium-sparing diuretics increase urine output without increasing potassium loss. Potassium-sparing diuretics include spironolactone (Aldactone, Novospiron ♣), triamterene (Dyrenium), and amiloride (Midamor).

Nutrition therapy involves coordination with a dietitian to teach the patient how to increase dietary potassium intake. Eating foods that are naturally rich in potassium helps prevent further loss, but supplementation is needed to restore normal potassium levels when hypokalemia is present.

Implement safety measures with a patient who has muscle weakness from hypokalemia, including the falls precautions listed in [Chart 13-4](#). Measures include eliminating hazards and assisting with ambulation. Instruct UAP to remove obstacles or slippery areas from the ambulation path, and make certain the patient wears nonslip footwear. Be sure to have the patient wear a gait belt when ambulating with assistance.

Respiratory monitoring is performed at least hourly for severe hypokalemia and includes rate and depth, especially checking for increasing rate and decreasing depth. Also check oxygen saturation by pulse oximetry to determine breathing effectiveness. Assess respiratory muscle effectiveness by checking the patient's ability to cough. Examine the face, oral mucosa, and nail beds for pallor or cyanosis. Evaluate arterial blood gas values (when available) for decreased blood oxygen

? DECISION-MAKING CHALLENGE**Safety; Evidence-Based Practice**

The 75-year-old patient with hypokalemia described on p. 185 is receiving IV potassium replacement through a peripheral venous access in the left antecubital space. The IV contains 80 mEq of potassium chloride in 1000 mL of normal saline. It is infusing at a rate of 150 mL/hr using a controller. She reports pain and burning at the infusion site. When you check for a blood return, you find a blood return, but it is slow.

1. How should you manage this infusion? (Provide a rationale for your decision.)
2. How many mEq of potassium per hour is the patient receiving at this rate?
3. What clinical manifestations would indicate to you that she is responding well to this therapy?
4. What clinical manifestations would indicate to you that she is becoming hyperkalemic?
5. What dietary changes could this patient make to help ensure potassium balance?

TABLE 13-8 COMMON CAUSES OF HYPERKALEMIA**Actual Potassium Excesses**

- Overingestion of potassium-containing foods or medications:
 - Salt substitutes
 - Potassium chloride
 - Rapid infusion of potassium-containing IV solution
 - Bolus IV potassium injections
- Transfusions of whole blood or packed cells
- Adrenal insufficiency (Addison's disease, adrenalectomy)
- Kidney failure
- Potassium-sparing diuretics
- Angiotensin-converting enzyme inhibitors (ACEIs)

Relative Potassium Excesses

- Tissue damage
- Acidosis
- Hyperuricemia
- Uncontrolled diabetes mellitus

levels (**hypoxemia**) and increased arterial carbon dioxide levels (**hypercapnia**), which indicate inadequate breathing effectiveness.

HYPERKALEMIA**Pathophysiology**

Hyperkalemia is a serum potassium level higher than 5.0 mEq/L (mmol/L). The normal range for serum potassium values is narrow, so even slight increases above normal values can affect excitable tissues, especially the heart.

A high serum potassium level decreases the potassium difference between the intracellular fluid (ICF) and the extracellular fluid (ECF). This decreased difference increases cell excitability; as a result, most excitable tissues respond to less intense stimuli and may even discharge spontaneously. The heart is very sensitive to serum potassium increases, and the most serious complications of hyperkalemia are heart block and ventricular fibrillation.

The problems that occur with hyperkalemia are related to how rapidly ECF potassium levels increase. Sudden rises in serum potassium cause severe problems at potassium levels between 6 and 7 mEq/L. When serum potassium rises slowly, problems may not occur until potassium levels reach 8 mEq/L or higher.

Hyperkalemia may result from an actual increase in total body potassium or from the movement of potassium from the cells into the blood. Hyperkalemia is rare in people with normal kidney function. Most cases of hyperkalemia occur in hospitalized patients and in those undergoing medical treatment. Those at greatest risk for hyperkalemia are chronically ill patients, debilitated patients, and older adults. [Table 13-8](#) lists common causes of hyperkalemia.

PATIENT-CENTERED COLLABORATIVE CARE**ASSESSMENT**

Age is important because kidney function decreases with aging. Ask about chronic illnesses (particularly kidney disease and diabetes mellitus), recent medical or surgical treatment,

and urine output, including frequency and amount of voidings. Ask about drug use, particularly potassium-sparing diuretics and angiotensin-converting enzyme (ACE) inhibitors. Obtain a nutrition history to determine the intake of potassium-rich foods and the use of salt substitutes (which contain potassium).

Collect specific information about symptoms related to hyperkalemia. Ask whether the patient has had palpitations, skipped heartbeats, other cardiac irregularities, muscle twitching, weakness in the leg muscles, or unusual tingling or numbness in the hands, feet, or face. Ask about recent changes in bowel habits, especially diarrhea.

Cardiovascular changes are the most severe problems from hyperkalemia and are the most common cause of death in patients with hyperkalemia. Cardiac manifestations of hyperkalemia include bradycardia, hypotension, and ECG changes of tall, peaked T waves, prolonged PR intervals, flat or absent P waves, and wide QRS complexes. As serum potassium levels rise, heartbeats generated outside the normal conduction system in the ventricles (**ectopic beats**) may appear. Complete heart block, asystole, and ventricular fibrillation are life-threatening complications of severe hyperkalemia.

Neuromuscular changes with hyperkalemia have two phases. Skeletal muscles twitch in the early stages of hyperkalemia, and the patient may be aware of tingling and burning sensations followed by numbness in the hands and feet and around the mouth (**paresthesia**). As hyperkalemia worsens, muscle twitching changes to weakness followed by flaccid paralysis. The weakness moves up from the hands and feet and first affects the muscles of the arms and legs. Respiratory muscles are not affected until serum potassium levels reach lethal levels.

Intestinal changes include increased motility. The patient may have diarrhea and spastic colonic activity. Bowel sounds are hyperactive, with audible rushes and gurgles. Bowel movements are frequent and watery.

Laboratory data confirm hyperkalemia (potassium level over 5.0 mEq/L). If it is caused by dehydration, levels of other electrolytes, hematocrit, and hemoglobin also are elevated. Hyperkalemia caused by kidney failure occurs with elevated serum creatinine and blood urea nitrogen, decreased blood pH, and normal or low hematocrit and hemoglobin levels.

INTERVENTIONS

Interventions for hyperkalemia focus on rapidly reducing the serum potassium level, preventing recurrences, and ensuring patient safety during the electrolyte imbalance. Drug therapy is the main medical intervention. *The priorities for nursing care of the patient with hyperkalemia are monitoring to prevent cardiac complications, patient safety for falls prevention, monitoring the patient's response to therapy, and health teaching.*

Drug therapy can restore normal potassium balance by enhancing potassium excretion and promoting the movement of potassium from the extracellular fluid (ECF) into the cells.

Eliminate extra potassium by stopping potassium-containing infusions. Keeping the IV access open is useful in managing hyperkalemia. Withhold oral potassium supplements, and provide a potassium-restricted diet.

Increasing potassium excretion helps reduce hyperkalemia if kidney function is normal. Potassium-excreting diuretics, such as furosemide, are prescribed. For a patient with kidney

problems, drug therapy to increase potassium excretion includes cation exchange resins that promote intestinal sodium absorption and potassium excretion, such as sodium polystyrene sulfonate (Kayexalate). However, this therapy may take many hours to reduce potassium levels. If potassium levels are dangerously high, additional measures, such as dialysis, are needed.

Movement of potassium from the extracellular fluid (ECF) to the intracellular fluid (ICF) can help reduce serum potassium levels temporarily. Potassium movement into the cells is enhanced by insulin. Insulin increases the activity of the sodium-potassium pumps, which move potassium from the ECF into the cell. IV fluids containing glucose and insulin are prescribed to help decrease serum potassium levels (usually 100 mL of 10% to 20% glucose with 10 to 20 units of regular insulin). These IV solutions are hypertonic and are infused through a central line or in a vein with a high blood flow to avoid local vein inflammation. Observe the patient for manifestations of hypokalemia and hypoglycemia during this therapy.

Cardiac monitoring allows for the early recognition of dysrhythmias and other manifestations of hyperkalemia on cardiac muscle. Compare recent ECG tracings with the patient's baseline tracings or with tracings obtained when the patient's serum potassium level was close to normal.

! NURSING SAFETY PRIORITY

Critical Rescue

Notify the health care provider or Rapid Response Team if the patient's heart rate falls below 60 beats per minute or if the T waves become spiked, both of which accompany hyperkalemia.

Health teaching is key to the prevention of hyperkalemia and the early detection of complications. The teaching plan for the patient at risk for hyperkalemia includes diet, drugs, and recognition of the manifestations of hyperkalemia. Collaborate with the dietitian to teach the patient and family about which foods to avoid (those high in potassium). Foods that contain little potassium and are allowed are listed in [Chart 13-8](#). Instruct the patient and family to read the labels on drug and food packages to determine the potassium content. Warn them to avoid salt substitutes, which contain potassium.

? NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

The client receiving insulin and glucose infusion therapy for hyperkalemia now has a serum potassium level of 4.7 mEq/L. What is the nurse's best first action?

- A. Assess the client's respiratory status and then notify the Rapid Response Team.
- B. Stop the infusion and discontinue the IV access.
- C. Continue the infusion at the prescribed rate.
- D. Slow the infusion and notify the health care provider.

CALCIUM

Calcium (Ca^{2+}) is a mineral with functions closely related to those of phosphorus and magnesium. Calcium is an ion having two positive charges (**divalent cation**) that exists in

CHART 13-8 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Nutritional Management of Hyperkalemia

You Should Avoid

- Meats, especially organ meat and preserved meat
- Dairy products
- Dried fruit
- Fruits high in potassium:
 - Bananas
 - Cantaloupe
 - Kiwi
 - Oranges
- Vegetables high in potassium:
 - Avocados
 - Broccoli
 - Dried beans or peas
 - Lima beans
 - Mushrooms
 - Potatoes (white or sweet)
 - Seaweed
 - Soybeans
 - Spinach
- Cereals
- Sugar
- Fruits low in potassium (fresh, frozen, or canned):
 - Apples
 - Apricots
 - Berries
 - Cherries
 - Cranberries
 - Grapefruit
 - Peaches
 - Pineapple
- Vegetables low in potassium:
 - Alfalfa sprouts
 - Cabbage
 - Carrots
 - Cauliflower
 - Celery
 - Eggplant
 - Green beans
 - Lettuce
 - Onions
 - Peas
 - Peppers
 - Squash

You May Eat:

- Eggs
- Breads
- Butter

Data from Pennington, J. (2004). *Bowes and Church's food values of portions commonly used* (18th ed.). Philadelphia: Lippincott-Raven.

the body in a bound form and an ionized (unbound or free) form.

Bound calcium is usually attached to serum proteins, especially albumin. Ionized calcium is present in the blood and other extracellular fluid (ECF) as free calcium. Free calcium is the active form and must be kept within a narrow range in the ECF. The body functions best when blood calcium levels are maintained between 9.0 and 10.5 mg/dL, or between 2.25 and 2.75 mmol/L (see Table 13-1). Calcium has a steep gradient between ECF and intracellular fluid (ICF) because the amount of calcium in the ICF is very low. This mineral is important for maintaining bone strength and density, activating enzymes, allowing skeletal and cardiac muscle contraction, controlling nerve impulse transmission, and allowing blood clotting.

Calcium enters the body by dietary intake and absorption through the intestinal tract. Dairy products are common foods high in calcium. Absorption of dietary calcium requires the active form of vitamin D. Calcium is stored in the bones. When both plasma calcium levels and stored calcium levels are adequate, intestinal absorption of dietary calcium is reduced and urine excretion of excess calcium increases. When more calcium is needed, parathyroid hormone (PTH) is released from the parathyroid glands. PTH increases serum calcium levels by:

- Releasing free calcium from bone storage sites (bone resorption of calcium)

- Stimulating vitamin D activation to help increase intestinal absorption of dietary calcium
- Inhibiting kidney calcium excretion
- Stimulating kidney calcium reabsorption

When excess calcium is present in plasma, PTH secretion is inhibited and the secretion of *thyrocalcitonin* (TCT), a hormone secreted by the thyroid gland, is increased. TCT causes the plasma calcium level to decrease by inhibiting bone resorption of calcium, inhibiting vitamin D–associated intestinal uptake of calcium, and increasing kidney excretion of calcium in the urine.

HYPOCALCEMIA

Pathophysiology

Hypocalcemia is a total serum calcium (Ca^{2+}) level below 9.0 mg/dL, or 2.25 mmol/L. Calcium is stored in bone, with only a small amount of total body calcium present in extracellular fluid (ECF). Because the normal blood level of calcium is so low, any change in calcium levels has major effects on function.

Calcium is an excitable membrane stabilizer, regulating depolarization and the generation of action potentials. It decreases sodium movement across excitable membranes, slowing the rate of depolarization. Low serum calcium levels increase sodium movement across excitable membranes, allowing depolarization to occur more easily and at inappropriate times.

Hypocalcemia is caused by many chronic and acute conditions, as well as medical or surgical treatments. Table 13-9 lists the common causes of hypocalcemia. Acute hypocalcemia results in the rapid onset of life-threatening manifestations, even when the serum calcium level is not very low. Chronic hypocalcemia occurs slowly over time, and excitable membrane manifestations may not be severe because the body has adjusted to the gradual reduction of serum calcium levels.

CULTURAL AWARENESS

Lactose intolerance caused by a deficiency of the enzyme *lactase* occurs in 75% to 90% of all Asians, Blacks, and American Indians (McCance et al., 2010). Although this problem also does occur in Caucasians, the incidence is much higher in nonwhites. People with lactose intolerance cannot use the nutrients in milk and have cramping, diarrhea, and abdominal pain after ingesting dairy products. Dairy products, especially milk, are common and rich sources of both calcium and vitamin D. People with lactose intolerance may, therefore, have difficulty obtaining enough calcium and vitamin D from other sources to maintain normal calcium levels in the blood and bones.

WOMEN'S HEALTH CONSIDERATIONS

Postmenopausal women are at risk for chronic calcium loss. This problem is related to reduced weight-bearing activities and a decrease in estrogen levels. In general, women have smaller frames than men and the female skeleton does not bear as much weight as the male skeleton. As they age, many women decrease weight-bearing activities such as running and walking, which allows osteoporosis to occur at a more rapid rate. Also, the estrogen secretion that protects against osteoporosis diminishes. (See Chapter 53 for a complete discussion of osteoporosis.)

TABLE 13-9 COMMON CAUSES OF HYPOCALCEMIA**Actual Calcium Deficits**

- Inadequate oral intake of calcium
- Lactose intolerance
- Malabsorption syndromes:
 - Celiac sprue
 - Crohn's disease
- Inadequate intake of vitamin D
- End-stage kidney disease
- Kidney failure—polyuric phase
- Diarrhea
- Steatorrhea
- Wound drainage (especially gastrointestinal)

Relative Calcium Deficits

- Hyperproteinemia
- Alkalosis
- Calcium chelators or binders
- Citrate
- Mithramycin
- Penicillamine
- Sodium cellulose phosphate (Calcibind)
- Aredia
- Acute pancreatitis
- Hyperphosphatemia
- Immobility
- Removal or destruction of parathyroid glands

Actual calcium loss (a reduction in total body calcium) occurs when the absorption of calcium from the GI tract slows or when calcium is lost from the body. Relative calcium loss causes total body calcium amounts to remain normal while serum calcium levels are low. This problem occurs when the unbound calcium in the body is reduced or when parathyroid gland function is decreased.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

The nutrition history is important to assess for the risk for hypocalcemia. Ask the patient about his or her intake of dairy products and whether he or she takes a calcium supplement regularly.

One indicator of hypocalcemia is a report of frequent, painful muscle spasms (“charley horses”) in the calf or foot during rest or sleep. Other information that indicates possible hypocalcemia is a history of recent orthopedic surgery or bone healing. Endocrine disturbances and treatments are risk factors for hypocalcemia. A history of thyroid surgery, therapeutic irradiation of the upper middle chest and neck area, or a recent anterior neck injury increases the risk for hypocalcemia. Most manifestations of acute hypocalcemia are caused by overstimulation of the nerves and muscles.

Neuromuscular changes often occur first in the hands and feet. Paresthesias occur at first, with sensations of tingling and numbness. If hypocalcemia continues or worsens, actual muscle twitching or painful cramps and spasms occur. Tingling may also affect the lips, nose, and ears. These problems

FIG. 13-14 Palmar flexion indicating a positive Trousseau's sign in hypocalcemia.

FIG. 13-15 Facial muscle response indicating a positive Chvostek's sign in hypocalcemia.

may signal the onset of neuromuscular overstimulation and tetany.

Assess for hypocalcemia by testing for Trousseau's and Chvostek's signs. To test for Trousseau's sign, place a blood pressure cuff around the upper arm, inflate the cuff to greater than the patient's systolic pressure, and keep the cuff inflated for 1 to 4 minutes. Under these hypoxic conditions, a positive Trousseau's sign occurs when the hand and fingers go into spasm in palmar flexion (Fig. 13-14). To test for Chvostek's sign, tap the face just below and in front of the ear (over the facial nerve) to trigger facial twitching of one side of the mouth, nose, and cheek (Fig. 13-15).

Cardiovascular changes involve heart rate and ECG changes. The heart rate may be slower or slightly faster than normal, with a weak, thready pulse. Severe hypocalcemia causes severe hypotension and ECG changes of a prolonged ST interval and a prolonged QT interval.

Intestinal changes include increased peristaltic activity. Auscultate the abdomen for hyperactive bowel sounds. The patient may report painful abdominal cramping and diarrhea.

Skeletal changes are most common with chronic hypocalcemia. Calcium is moved from bone storage sites, causing a loss of bone density (osteoporosis). The bones are less dense, more brittle, and fragile. These bones break easily with even slight trauma. Vertebrae become more compact and may bend forward, leading to an overall loss of height. See [Chapter 53](#) for more discussion about osteoporosis.

Ask about changes in height and any unexplained bone pain. Observe for spinal curvatures and any unusual bumps or protrusions in bones that may indicate old fractures.

INTERVENTIONS

Interventions focus on restoring normal calcium levels and preventing complications. These include drug therapy, nutrition therapy, reducing environmental stimuli, and preventing injury. Patient safety during restoration of serum calcium levels is a priority of nursing care.

Drug therapy for hypocalcemia includes direct calcium replacement (oral and IV) and drugs that enhance the absorption of calcium, such as aluminum hydroxide and vitamin D. When neuromuscular manifestations are troublesome, drugs that decrease nerve and muscle responses also may be used. These drugs may include magnesium sulfate and various muscle relaxants.

Nutrition therapy involves a high-calcium diet for patients with mild hypocalcemia and for those with chronic conditions that cause them to be at continuous risk for hypocalcemia. Coordinate with the dietitian to assist the patient in selecting calcium-rich foods.

Environmental management for safety is needed because the excitable membranes of the nervous system and the skeletal system are overstimulated in hypocalcemia. Interventions to reduce stimulation include keeping the room quiet, limiting visitors, adjusting the lighting, and using a soft but reassuring voice.

Use seizure precautions for the patient with hypocalcemia. Such precautions include either keeping the bed in the lowest possible position and the siderails of the bed in the “up” position. Alternately, a mattress can be placed on the floor on the side of the bed with the siderail down. Keep emergency equipment (e.g., oxygen, suction) at the bedside. Keep an emergency cart equipped with emergency drugs and an endotracheal tray just outside the patient’s room. If the patient does not have an IV access, one should be started.

NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

The nurse takes the blood pressure of a client who is being treated for hypocalcemia. When the cuff is tightest, the client’s hand develops palmar flexion. After the cuff is deflated, the hand remains in palmar flexion. What is the nurse’s best first action?

- Apply oxygen.
- Alert the Rapid Response Team.
- Slow the calcium-containing IV solution.
- Turn the client onto the side opposite the hand with the flexion.

TABLE 13-10 COMMON CAUSES OF HYPERCALCEMIA

Actual Calcium Excesses

- Excessive oral intake of calcium
- Excessive oral intake of vitamin D
- Kidney failure
- Use of thiazide diuretics

Relative Calcium Excesses

- Hyperparathyroidism
- Malignancy:
 - Direct invasion (cancers of breast, lung, prostate, and osteoclastic bone and multiple myeloma)
 - Indirect resorption (liver cancer, small cell lung cancer, and cancer of the adrenal gland)
- Hyperthyroidism
- Immobility
- Use of glucocorticoids
- Dehydration

Injury prevention strategies are needed because the patient with long-standing calcium loss may have brittle, fragile bones that fracture easily and cause little pain. When lifting or moving a patient with fragile bones, use a lift sheet rather than pulling the patient. Observe for normal range of joint motion and for any unusual surface bumps or depressions over bony areas.

HYPERCALCEMIA

Pathophysiology

Hypercalcemia is a total serum calcium level above 10.5 mg/dL, or 2.75 mmol/L. Because the normal range for serum calcium is so narrow, even small increases have severe effects. Although the effects of hypercalcemia occur first in excitable tissues, all systems are affected.

Hypercalcemia means either that the amount of serum calcium is so great that the normal calcium-controlling mechanisms cannot keep pace or that at least one control mechanism is not functioning properly ([Table 13-10](#)). Hypercalcemia causes excitable tissues to be less sensitive to normal stimuli, thus requiring a stronger stimulus to function. The excitable tissues affected most by hypercalcemia are the heart, skeletal muscles, nerves, and intestinal smooth muscles.

Calcium is needed by many of the enzymes involved in blood clotting. Hypercalcemia causes faster clotting times. Clots may form when they are not needed to control bleeding. Excessive clotting from hypercalcemia occurs more easily in vessels with slow blood flow.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

The manifestations of hypercalcemia are related to its severity and how quickly the imbalance occurred. The patient with a mild but rapidly occurring calcium excess usually has more severe problems than the patient whose imbalance is severe but has developed slowly.

Cardiovascular changes are the most serious and life-threatening problems of hypercalcemia. Mild hypercalcemia at first causes increased heart rate and blood pressure. Severe or prolonged calcium imbalance depresses electrical conduction, slowing heart rate.

Measure pulse rate and blood pressure, and observe for indications of poor tissue blood flow, such as cyanosis and pallor. Examine ECG tracings for dysrhythmias, especially a shortened QT interval.

Hypercalcemia allows blood clots to form more easily whenever blood flow is poor. Blood clotting is more likely in the lower legs, the pelvic region, areas where blood flow is blocked by internal or external constrictions, and areas where venous obstruction occurs.

Assess for slowed or impaired blood flow. Measure and record calf circumferences with a soft tape measure. Assess the feet for temperature, color, and capillary refill to determine the blood flow to and from the area.

Neuromuscular changes include severe muscle weakness and decreased deep tendon reflexes without paresthesia. The patient may have an altered level of consciousness that can range from confusion and lethargy to coma. Psychiatric problems also can occur.

Intestinal changes are first reflected as decreased peristalsis. Constipation, anorexia, nausea, vomiting, and abdominal pain are common. Bowel sounds are hypoactive or absent. The abdomen increases in size because the intestinal contents remain in the tract instead of being moved forward. Assess abdominal size by measuring abdominal girth with a soft tape measure in a line circling the abdomen at the umbilicus.

INTERVENTIONS

Interventions for hypercalcemia aim to reduce serum calcium levels through drug therapy and dialysis. Rehydration and cardiac monitoring are also important.

Drug therapy involves preventing increases in calcium, as well as drugs to lower calcium levels. IV solutions containing calcium (e.g., Ringer's lactate) are stopped. Oral drugs containing calcium or vitamin D (e.g., calcium-based antacids) are discontinued.

Fluid volume replacement can help restore normal serum calcium levels. IV normal saline (0.9% sodium chloride) is usually given because sodium increases kidney excretion of calcium.

Thiazide diuretics are discontinued and are replaced with diuretics that enhance the excretion of calcium, such as furosemide (Lasix, Furoside 🍁). Calcium chelators (calcium binders) help lower serum calcium levels. Such drugs include plicamycin (Mithracin) and penicillamine (Cuprimine, Pendramine 🍁).

Drugs to prevent hypercalcemia include agents that inhibit calcium resorption from bone, such as phosphorus, calcitonin (Calcimar), bisphosphonates (etidronate), and prostaglandin synthesis inhibitors (aspirin, NSAIDs).

Dialysis is used when severe hypercalcemia causes life-threatening cardiac problems and drug therapy may not reduce serum calcium levels fast enough to prevent death. Methods of dialysis for rapid calcium reduction are usually hemodialysis or blood ultrafiltration.

Cardiac monitoring of patients with hypercalcemia is needed to identify dysrhythmias and decreased cardiac

output. Compare recent ECG tracings with the patient's baseline tracings. Especially look for changes in the T waves and the QT interval and changes in rate and rhythm.

PHOSPHORUS

Phosphorus (P) is in the body in both inorganic and organic forms. Normal serum levels of phosphorus range from 3.0 to 4.5 mg/dL, or 0.97 to 1.45 mmol/L (see Table 13-1). Most phosphorus (80%) can be found in the bones. It is the major anion in the ICF, and its levels inside cells are much higher than in the ECF. Phosphorus is needed for activating vitamins and enzymes, forming adenosine triphosphate (ATP) for energy supplies, and assisting in cell growth and metabolism. It also functions in acid-base balance and calcium homeostasis.

The average North American diet is high in phosphorus (1 to 2 g/day). Food sources of phosphorus include meats, fish, dairy products, and nuts.

Phosphorus balance and calcium balance are intertwined. Plasma levels of calcium and phosphorus exist in a balanced, reciprocal relationship, which means that when you multiply the two values, the product remains constant. Therefore a change in the amount of plasma phosphorus results in an equal and opposite change in the amount of plasma calcium (and vice versa).

The regulation of ECF phosphorus occurs through the activity of parathyroid hormone (PTH). Increased PTH levels cause a net loss of phosphorus. Reduced PTH levels enhance kidney reabsorption of phosphorus, resulting in increased plasma levels of phosphorus.

HYPOPHOSPHATEMIA

Pathophysiology

Hypophosphatemia is a serum phosphorus level below 3.0 mg/dL. Even though the serum level has a narrow range of normal (3.0 to 4.5 mg/dL), body functions are not usually impaired with rapid, wide changes in serum phosphorus levels. Reduced function occurs more often with chronic hypophosphatemia.

Most of the effects of hypophosphatemia are related to decreased energy metabolism and imbalances of other electrolytes and body fluids. Because of the relationship between phosphorus and calcium, *decreases* in serum phosphorus levels cause *increases* in serum calcium levels.

Three main processes lead to decreased serum phosphorus levels: decreased absorption of phosphorus, increased excretion of phosphorus, and intracellular phosphorus shift (Table 13-11).

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Manifestations occur when low serum phosphorus levels are severe or prolonged. They are related to the decreased amounts of high-energy compounds (e.g., adenosine triphosphate [ATP]) needed for normal metabolism. Manifestations are most apparent in the cardiac, musculoskeletal, hematologic, and central nervous systems.

TABLE 13-11 COMMON CAUSES OF PHOSPHORUS IMBALANCE**Hypophosphatemia**

- Malnutrition
- Starvation
- Use of aluminum hydroxide-based antacids
- Use of magnesium-based antacids
- Hyperparathyroidism
- Hypercalcemia
- Kidney failure
- Malignancy
- Hyperglycemia
- Hyperalimentation
- Respiratory alkalosis
- Uncontrolled diabetes mellitus
- Alcohol abuse

Hyperphosphatemia

- Decreased kidney excretion resulting from kidney disease
- Tumor lysis syndrome
- Increased intake of phosphorus
- Hypoparathyroidism

Cardiac changes include decreased stroke volume and decreased cardiac output. Peripheral pulses are slow, difficult to find, and easy to block. Cardiac depression is caused by low stores of intracellular energy. Without sufficient energy in myocardial cells, contractions are weak and ineffective. Prolonged hypophosphatemia causes progressive but reversible cardiac muscle damage.

Musculoskeletal changes include weak skeletal muscles that may progress to acute muscle breakdown (**rhabdomyolysis**). The weakness is generalized, and paresthesias usually are not present. When muscle weakness becomes profound, respiratory movements are ineffective, leading to respiratory failure. Assess for muscle strength, and observe respiratory effort.

The manifestations of *chronic* hypophosphatemia are most evident in the skeletal system. Bone density is decreased, which leads to fractures and changes in bone shape. These changes are caused by the bone calcium loss that occurs with hypophosphatemia. Assess the patient for unusual lumps or depressions over bony areas that indicate bone fractures.

Central nervous system changes are not apparent until hypophosphatemia is severe. These first appear as irritability and may progress to seizure activity followed by coma.

INTERVENTIONS

Drugs that promote phosphorus loss (e.g., antacids, osmotic diuretics, calcium supplements) are discontinued. Oral replacement of phosphorus along with a vitamin D supplement may correct moderate hypophosphatemia. IV phosphorus is given only when serum phosphorus levels fall below 1 mg/dL and the patient has serious manifestations. Infuse IV phosphorus slowly because the problems caused by hyperphosphatemia are equally serious.

Nutrition therapy involves increasing the intake of phosphorus-rich foods while decreasing the intake of calcium-rich foods (**Chart 13-9**). Collaborate with the dietitian to teach the patient and family which foods to eat and which to avoid.

CHART 13-9 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT**Nutritional Management of Hypophosphatemia**

YOU SHOULD AVOID	YOU MAY EAT
• Milk • Cheese • Yogurt • Collard greens • Rhubarb	• Fish • Beef • Chicken • Pork • Organ meats • Nuts • Whole-grain breads and cereals

HYPERPHOSPHATEMIA

Hyperphosphatemia is a serum phosphorus level above 4.5 mg/dL. High levels are well tolerated by most body systems.

The problems caused by hyperphosphatemia center on the hypocalcemia that results when serum phosphorus levels increase. These problems include increased membrane excitability (see pp. 188-190).

Causes of increased serum phosphorus levels include kidney disease, certain cancer treatments, increased phosphorus intake, and hypoparathyroidism. **Table 13-11** lists common causes of hyperphosphatemia.

Hyperphosphatemia causes few direct problems with body function. However, hypocalcemia is usually present because calcium and phosphorus exist in the blood in a balanced reciprocal relationship: when one increases, the other decreases. The hypocalcemia greatly alters many body system functions and can cause life-threatening side effects. Thus the management of hyperphosphatemia entails the management of hypocalcemia (see p. 190).

MAGNESIUM

Magnesium (Mg^{2+}) is a mineral that forms a cation when dissolved in water. Adults have an average total body level of 25 g of magnesium, most of which (60%) is stored in bones and cartilage. Little magnesium is present in the extracellular fluid (ECF). Plasma levels of free magnesium range from 1.3 to 2.1 mEq/L, or 0.65 to 1.05 mmol/L (see **Table 13-1**). Much more magnesium is present in the intracellular fluid (ICF), and it has more functions inside the cells than in the blood. Magnesium is critical for skeletal muscle contraction, carbohydrate metabolism, adenosine triphosphate (ATP) formation, vitamin activation, and cell growth. Extracellular magnesium regulates blood coagulation and skeletal muscle contractility.

The daily magnesium requirement for adults is about 300 mg. Magnesium is present in low levels in most foods.

Magnesium regulation occurs through the kidney and the intestinal tract although the exact mechanisms are not known. When blood magnesium levels are low, ingested magnesium is rapidly absorbed and kidney excretion of magnesium stops. When blood magnesium levels are high, little magnesium is absorbed from food and kidney magnesium excretion increases.

TABLE 13-12 COMMON CAUSES OF MAGNESIUM IMBALANCE**Hypomagnesemia**

- Malnutrition
- Starvation
- Diarrhea
- Steatorrhea
- Celiac disease
- Crohn's disease
- Drugs (diuretics, aminoglycoside antibiotics, cisplatin, amphotericin B, cyclosporine)
- Citrate (blood products)
- Ethanol ingestion

Hypermagnesemia

- Increased magnesium intake:
 - Magnesium-containing antacids and laxatives
 - IV magnesium replacement
- Decreased kidney excretion of magnesium resulting from kidney disease

HYPOMAGNESEMIA**Pathophysiology**

Hypomagnesemia is a serum magnesium (Mg^{2+}) level below 1.3 mEq/L. Most problems leading to hypomagnesemia are caused by decreased magnesium intake or increased magnesium loss. As a result, hypomagnesemia reflects a decrease in the total body magnesium content.

The effects of hypomagnesemia are caused by increased membrane excitability and the accompanying serum calcium and potassium imbalances. Excitable membranes, especially nerve cell membranes, may depolarize spontaneously.

Hypomagnesemia is caused by decreased absorption of dietary magnesium or increased kidney magnesium excretion. Table 13-12 lists the specific causes of hypomagnesemia.

PATIENT-CENTERED COLLABORATIVE CARE

Common clinical manifestations of hypomagnesemia are seen in the neuromuscular, central nervous, and intestinal systems.

Neuromuscular changes are caused by increased nerve impulse transmission. Normally, magnesium inhibits nerve impulse transmission at synapse areas. Decreased levels increase impulse transmission from nerve to nerve or from nerve to skeletal muscle. The patient has hyperactive deep tendon reflexes, numbness and tingling, and painful muscle contractions. Positive Chvostek's and Trousseau's signs may be present because hypomagnesemia may occur with hypocalcemia (see the earlier discussion of these assessment signs of neuromuscular changes on pp. 189-190 in the *Hypocalcemia* section). Skeletal muscle weakness occurs when intracellular magnesium levels are also decreased. The patient may have tetany and seizures as hypomagnesemia worsens.

Central nervous system (CNS) changes are caused by increased nerve impulse transmission. These changes may present as psychological depression, psychosis, and confusion.

Intestinal changes are from decreased intestinal smooth muscle contraction. Reduced motility, anorexia, nausea, constipation, and abdominal distention are common. A paralytic ileus may occur when hypomagnesemia is severe.

Interventions for hypomagnesemia aim to correct the imbalance and manage the specific problem that caused it. In addition, because hypocalcemia often occurs with hypomagnesemia, interventions also aim to restore normal serum calcium levels.

Drugs that promote magnesium loss, such as high-ceiling (loop) diuretics, osmotic diuretics, aminoglycoside antibiotics, and drugs containing phosphorus, are discontinued. Magnesium is replaced intravenously with magnesium sulfate (MgSO_4) when hypomagnesemia is severe. *The IV route is used because MgSO_4 causes pain and tissue damage when injected IM.* Assess deep tendon reflexes at least hourly in the patient receiving IV magnesium to monitor effectiveness and prevent hypermagnesemia. Oral magnesium often causes diarrhea and can increase magnesium loss. If hypocalcemia is also present, drug therapy to increase serum calcium levels is prescribed.

HYPERMAGNESEMIA**Pathophysiology**

Hypermagnesemia is a serum magnesium level above 2.1 mEq/L. Magnesium is a membrane stabilizer. When magnesium excess occurs, excitable membranes are less excitable and need a stronger-than-normal stimulus to respond. With severe hypermagnesemia, excitable membranes may not respond to any stimulus.

The imbalance results from increased intake of magnesium coupled with decreased kidney excretion of magnesium. Table 13-12 lists the specific causes of hypermagnesemia.

PATIENT-CENTERED COLLABORATIVE CARE

Most manifestations of hypermagnesemia occur as a result of reduced membrane excitability. They usually are not apparent until serum magnesium levels exceed 4 mEq/L. The most common problems are seen in the cardiac, central nervous, and neuromuscular systems.

Cardiac changes include bradycardia, peripheral vasodilation, and hypotension. These problems become more severe as serum magnesium levels increase. ECG changes show a prolonged PR interval with a widened QRS complex. Bradycardia can be severe, and cardiac arrest is possible. Hypotension is also severe, with a diastolic pressure lower than normal. *Patients with severe hypermagnesemia are in grave danger of cardiac arrest.*

Central nervous system changes result from depressed nerve impulse transmission. Patients may be drowsy or lethargic. Coma may occur if the imbalance is prolonged or severe.

Neuromuscular changes result from decreased nerve impulse transmission to the skeletal muscles. Deep tendon reflexes are reduced or even absent. Voluntary skeletal muscle contractions become progressively weaker and finally stop.

Hypermagnesemia has no direct effect on the lungs; however, when the respiratory muscles are weak, respiratory insufficiency can lead to respiratory failure and death.

Interventions for hypermagnesemia aim to reduce the serum level and correct the underlying problem that caused the imbalance.

All oral and parenteral magnesium is discontinued. When kidney failure is not present, giving magnesium-free IV fluids can reduce serum magnesium levels. High-ceiling (loop) diuretics such as furosemide (Lasix, Furoside ) can further reduce serum magnesium levels. When cardiac problems are severe, giving calcium may reverse the cardiac effects of hypermagnesemia.

CHLORIDE

Chloride (Cl^-) is the major anion of the extracellular fluid (ECF) and works with sodium to maintain ECF osmotic pressure. Chloride is important in the formation of hydrochloric acid in the stomach. The normal plasma concentration of chloride ranges from 98 to 106 mEq/L (mmol/L) (see Table 13-1).

Only a small amount of chloride is present inside the cells because negative charges on the cell membrane repel chloride and prevent it from crossing the membrane. However, extracellular chloride can enter cells when exchanged for another anion that is leaving the cell. This situation, called a *chloride shift*, decreases plasma chloride without a net body loss of chloride. Bicarbonate (HCO_3^-) is the anion most commonly exchanged for chloride.

Chloride enters the body through dietary intake. Because chloride (along with sodium, potassium, and many other minerals) is a part of a salt, most diets contain enough chloride to meet the normal needs of the body.

Imbalances of chloride usually occur as a result of other electrolyte imbalances. An exception is chloride loss from excessive vomiting or prolonged gastric suction. Imbalances of chloride are usually corrected by interventions for correcting other electrolyte or acid-base problems.

GET READY FOR THE NCLEX® EXAMINATION!

KEY POINTS

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Assess any patient with a fluid or electrolyte imbalance for falls risk.
- Ensure access to adequate fluids for patients who cannot talk or who have limited mobility.
- Use a pump or controller to deliver IV fluids to patients with fluid overload.
- Do not give IV potassium at a rate greater than 20 mEq/hr.
- Never give potassium supplements by the IM, subcutaneous, or IV push routes.
- Use a pump or controller when giving IV potassium-containing solutions.
- Use a gait belt when assisting a patient with muscle weakness to walk or transfer.
- Collaborate with the dietitian to teach patients about diets that are restricted in potassium, sodium, or calcium.
- Use a lift sheet to move or reposition a patient with chronic hypocalcemia.

Health Promotion and Maintenance

- Encourage all patients to maintain an adequate fluid intake (minimum of 3 L per day) unless another condition requires fluid restriction.
- Teach all people to increase fluid intake when exercising, when in hot or dry environments, or during conditions that increase metabolism (e.g., fever).
- Instruct patients at risk for fluid imbalance to weigh themselves on the same scale daily, close to the same time each

day, and with about the same amount of clothing on each time and to monitor these daily weights for changes or trends.

- Instruct patients who exercise heavily (athletes) to take scheduled fluid replacement breaks.
- Instruct caregivers of older adults who have cognitive impairments or mobility problems to schedule offerings of fluids at regular intervals throughout the day.
- Teach patients how to determine electrolyte content of processed foods by reading labels.
- Teach patients who are prescribed to take diuretics to take the drugs as prescribed.
- Teach patients who are taking digoxin to measure their pulse for rate, rhythm, and quality.
- Teach patients who are taking diuretics to measure their pulse for rate, rhythm, and quality.
- Include the person who prepares the patient's meals when teaching about dietary electrolyte restrictions.

Psychosocial Integrity

- Explain the purpose of fluid restriction to the patient and the family to ensure cooperation and prevent any misunderstandings.
- Assess patients who have a sudden change in cognition for fluid and electrolyte imbalances.
- Determine the patient's food preferences and dislikes when planning an electrolyte-restricted diet.

Physiological Integrity

- Assess skin turgor on the forehead or the sternum of older patients.
- Use daily weights to determine fluid gains or losses.

GET READY FOR THE NCLEX® EXAMINATION! —cont'd

- Ask patients about the use of drugs such as diuretics, laxatives, salt substitutes, and antihypertensives that may alter fluid and electrolyte status.
- Correctly interpret laboratory electrolyte values.
- Do not give oral fluids to an unconscious patient.
- Monitor the cardiac and pulmonary status at least every hour when patients with dehydration are receiving IV fluid replacement therapy.
- Offer or ensure that oral care is performed at least every 4 hours for patients with dehydration.
- Assess the IV site hourly of a person receiving IV solutions containing potassium, and document its condition.
- Immediately stop the infusion of potassium-containing solutions if infiltration is suspected.
- Avoid administering magnesium sulfate by the IM route.
- Assess all patients with hyperkalemia for cardiac dysrhythmias and ECG abnormalities, especially tall T waves, conduction delays, and heart block.
- Assess the respiratory status of all patients with hypokalemia.
- Assess the bowel sounds; heart rate, rhythm, and quality; and muscle strength to evaluate the patient's responses to therapy for an electrolyte imbalance.

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Identify patients at risk for falls as a result of acid-base imbalances, especially older adults.

Physiological Integrity

2. Describe the relationship between free hydrogen ion level and pH.
3. Explain the concept of compensation.

4. Compare the roles of the respiratory system and the kidneys in maintaining acid-base balance.
5. Use laboratory data and clinical manifestations to determine the presence of acid-base imbalances.
6. Interpret arterial blood gases to determine whether acidosis is respiratory or metabolic in origin.
7. Prioritize nursing care for the patient with an acid-base imbalance.

Acid-base balance is the result of processes that carefully regulate hydrogen ion (H^+) production and elimination. Body fluid **pH** is a measure of the body fluid's free hydrogen ion level. *This value has the narrowest range of normal and the tightest control mechanisms of all the electrolytes.* The level of free hydrogen ions, formed from acids, must be rigidly controlled for proper function. Even small changes in the free hydrogen ion level, or pH, of body fluids can cause major problems in function. Keeping the pH within the normal range involves balancing acids and bases in body fluids. Normal pH ranges from 7.35 to 7.45 for arterial blood and from 7.31 to 7.41 for venous blood.

The normal free hydrogen ion level of blood and other body fluids is quite low (less than 0.0001 mEq/L) compared with the levels of other electrolytes (see [Chapter 13](#)). Because it is so low, it is not measured directly but, instead, is a calculated value. The pH value is calculated as the negative logarithm of the concentration in milliequivalents per liter. Because it is calculated in negative logarithm units, the value of pH is *inversely* related (negatively related) to the level of free hydrogen ions. In other words, the *lower* the pH value of a fluid, the *higher* the level of free hydrogen ions in that fluid. The pH of a solution may range from 1 (as acidic as possible)

to 14 (as alkaline as possible), with 7 being neutral. *A change of 1 pH unit actually represents a tenfold change in free hydrogen ion level.* Therefore any pH unit change (e.g., a change from 7.4 to 7.3) represents a very large increase in the free hydrogen ion level.

Keeping the pH of the blood within the normal range is important because changes from normal interfere with many functions. These include:

- Changing the shape and reducing the function of hormones and enzymes
- Changing the distribution of other electrolytes, causing fluid and electrolyte imbalances
- Changing excitable membranes, making the heart, nerves, muscles, and GI tract either less or more active than normal
- Decreasing the effectiveness of many drugs

Fortunately, the body has many mechanisms to ensure minimal changes in free hydrogen ion level.

ACID-BASE BALANCE

As discussed in [Chapter 13](#), body fluids are electrically neutral even though they contain ions with overall positive charges

FIG. 14-1 Release of hydrogen ions by a strong acid (hydrochloric acid) in which the strong acid completely dissociates in water.

FIG. 14-2 Release of hydrogen ions by a weak acid (acetic acid) in which the weak acid only partially dissociates in water and most of its hydrogen ions remain bound.

Fluid pH 7.38 (normal). The number and strength of acid components are equal to the number and strength of base components. Hydrogen ion concentration is limited and constant.

Fluid pH 7.51 (alkaline). The number and strength of base components are greater than the number and strength of acid components. Hydrogen ion concentration is below normal.

Buffer is added to the alkaline fluid.

The buffer acts as an acid, releasing a hydrogen ion.

FIG. 14-3 Action of buffer in solution.

and ions with overall negative charges. When fluids contain an equal number of positive and negative charges, the electrical charge of the fluid is balanced and remains neutral. The body keeps blood pH between 7.35 and 7.45 in a similar manner; however, this value is not strictly neutral (7.0 is neutral) but, rather, is slightly alkaline. Normal body fluid pH remains at a near-neutral value when the acids and bases are nearly balanced, limiting the total number of free or unbalanced hydrogen ions. Acid-base balance occurs by matching the rate of hydrogen ion production (which is a continuous normal process) with hydrogen ion loss.

ACID-BASE CHEMISTRY

Acids

Acids are substances that release hydrogen ions when dissolved in water (H_2O). An acid in solution *increases* the amount of free hydrogen ions in that solution. The strength of an acid is measured by how easily it releases a hydrogen ion in solution. A strong acid, such as hydrochloric acid (HCl), separates (**dissociates**) completely in water and readily releases *all* of its hydrogen ions (Fig. 14-1).

A weak acid does not completely separate in water; it releases only *some* of its hydrogen ions. In the following example, each molecule of acetic acid (CH_3COOH), a weak acid, contains a total of four hydrogen molecules. When

acetic acid combines with water (Fig. 14-2), it releases only one of its four hydrogen molecules. The other three hydrogen molecules remain bound to the acetic acid molecule (CH_3COO^-).

Bases

A **base** is a substance that binds free hydrogen ions in solution. Thus bases are “hydrogen acceptors” that *lower* the amount of free hydrogen ions in solution. Strong bases bind hydrogen ions easily. Examples of strong bases include sodium hydroxide (NaOH) and ammonia (NH_3).

Weak bases bind hydrogen ions less readily. Examples of weak bases are aluminum hydroxide ($\text{Al}(\text{OH})_3$) and bicarbonate (HCO_3^-). Although bicarbonate is a weak base, the many bicarbonate ions in the body are very important in preventing major changes in body fluid pH.

Buffers

Buffers are critical in keeping body fluid pH at normal levels because they can react in two ways: either as an acid (releasing a hydrogen ion) or as a base (binding a hydrogen ion). How a buffer reacts when dissolved in water depends on the existing acid-base balance of that fluid. Buffers always try to bring the fluid as close as possible to the normal body fluid pH of 7.35 to 7.45. If the fluid is basic (with few free hydrogen ions), the buffer *releases hydrogen ions* into the fluid (Fig. 14-3). If

the fluid is acidic (with many free hydrogen ions), the buffer acts as a base, *binding some of the excess hydrogen ions*. In this way, buffers act like hydrogen ion “sponges,” soaking up hydrogen ions when too many are present and squeezing out hydrogen ions when too few are present. This flexibility allows buffers to keep body fluid pH in the normal range.

Liquids with a pH of 7.0 are neutral; they have a free hydrogen ion level in which the amount and strength of acids and bases are equal. Fig. 14-4 shows the concept of neutral pH. This figure shows that the combined *strength* and *amount* of all acids are equal to the combined *strength* and *amount* of all bases in a given solution. This is close to the actual case in human physiology. With human acid-base homeostasis, the relative amounts and strengths of acids and bases are nearly equal and, normally, hydrogen ion production is balanced with hydrogen ion loss so that the overall free hydrogen ion levels remain constant.

Liquids with a pH ranging from 1.0 to 6.99 have more or stronger (or both) acids compared with the amount or strength (or both) of bases. These liquids are *acidic* (see Fig. 14-4), which means that more free hydrogen ions are being released than bound, increasing the amount of free hydrogen ions in the liquid.

Liquids with a pH ranging from 7.01 to 14.0 have more or stronger (or both) bases compared with the amount or strength (or both) of acids. These liquids are *basic*, which means that more hydrogen ions are being bound than released, decreasing the amount of free hydrogen ions (Fig. 14-5).

BODY FLUID CHEMISTRY

Bicarbonate Ions

Body fluids contain many different types of acids and a few types of bases. The most common base in human body fluid is bicarbonate (HCO_3^-); the most common acid is carbonic acid (H_2CO_3). In health, the body keeps these substances at a constant ratio of 1 molecule of carbonic acid to 20 free bicarbonate ions (1:20) (Fig. 14-6). To maintain this ratio, both carbonic acid and bicarbonate must be carefully controlled. This constant ratio is related to balancing the production and elimination of carbon dioxide (CO_2) and hydrogen ions (H^+).

FIG. 14-6 Normal ratio of carbonic acid to bicarbonate is 1:20.

FIG. 14-7 The carbonic anhydrase equation showing that the concentration of carbon dioxide is directly related to the concentration of hydrogen ions.

FIG. 14-8 Increased carbon dioxide levels force the equation to the right and increase the concentration of hydrogen ions proportionately.

Relationship Between Carbon Dioxide and Hydrogen Ions

A key concept in understanding acid-base balance is the *carbonic anhydrase equation*. This equation, driven by the enzyme *carbonic anhydrase*, shows how *hydrogen ion levels and carbon dioxide levels are directly related to one another, so that an increase in one causes an equal increase in the other* (Fig. 14-7).

Carbon dioxide is a gas that forms carbonic acid when combined with water, making carbon dioxide a part of carbonic acid. Carbonic acid is not stable, and the body needs to keep a 1:20 ratio of carbonic acid to bicarbonate. When carbonic acid is formed from water and carbon dioxide, it begins to separate into free hydrogen ions and bicarbonate ions. *Therefore the carbon dioxide content of a fluid is directly related to the amount of hydrogen ions in that fluid. Whenever conditions cause carbon dioxide to increase, more free hydrogen ions are created. Likewise, whenever free hydrogen ion production increases, more carbon dioxide is produced.*

When excess carbon dioxide is produced, the amount of carbon dioxide increases and the equation shifts to the right, causing an *increase* in hydrogen ions (and a *decrease* in pH), as shown in Fig. 14-8. When very little carbon dioxide is produced, no free hydrogen ions are created by this equation. When excess hydrogen ions are produced or brought into the body, the carbonic anhydrase equation shifts to the left, causing the creation of more carbon dioxide, as shown in Fig. 14-9. When the amount of free hydrogen ions in body fluids is low, no extra carbon dioxide is produced.

How is the relationship between free hydrogen ions and carbon dioxide helpful? Carbon dioxide is a gas that can be

CHART 14-1 LABORATORY PROFILE

Acid-Base Assessment

TEST	NORMAL RANGE FOR ADULTS		SIGNIFICANCE OF ABNORMAL FINDINGS
	ARTERIAL	VENOUS	
pH			
Adult <90 yr	7.35-7.45	7.31-7.41	Increased: metabolic alkalosis, loss of gastric fluids, decreased potassium intake, diuretic therapy, fever, salicylate toxicity, respiratory alkalosis, hyperventilation Decreased: metabolic or respiratory acidosis, ketosis, renal failure, starvation, diarrhea, hyperthyroidism
>90 yr	7.25-7.45	7.31-7.41	
PaO₂			
Adult <90 yr	80-100 mm Hg		Increased: increased ventilation, oxygen therapy, exercise Decreased: respiratory depression, high altitude, carbon monoxide poisoning, decreased cardiac output

FIG. 14-9 Increased hydrogen ion levels force the equation to the left and increase the concentration of carbon dioxide levels proportionately.

eliminated during exhalation, and this action is important for acid-base balance. When any condition causes the hydrogen ion concentration of body fluids to increase, extra CO₂ is produced in the same proportion. This extra CO₂ is eliminated during exhalation, helping to bring the hydrogen ion concentration down to normal. Whenever the CO₂ level changes, the pH changes to the same degree, in the opposite direction. Thus when the CO₂ level of a liquid increases, the pH drops, indicating more free hydrogen ions (more acidic). On the other hand, when the CO₂ level of a liquid decreases, the pH rises, indicating fewer free hydrogen ions (more alkaline).

An increase in bicarbonate causes the amount of hydrogen ions to decrease and the pH to increase, or become more alkaline (basic). On the other hand, an increase in the CO₂ level causes the free hydrogen ion level to increase and the pH to decrease, or become more acidic.

Because the kidneys control bicarbonate levels and the lungs control CO₂ levels in the healthy person, pH is also described as the function of the kidneys divided by the function of the lungs (Fig. 14-10).

Sources of Acids and Bicarbonate

Whenever acids are present in body fluids, free hydrogen ions are dissociated and must be controlled for pH balance. How are acids and hydrogen ions produced? Remember that whole body human function is dynamic and continuously working. The processes that allow the body to perform its work continuously generate acids and hydrogen ions as waste products of metabolism.

Normal metabolism of carbohydrate, protein, and fat creates natural waste products. Carbohydrate metabolism forms carbon dioxide (CO₂). Carbon dioxide is exhaled by the lungs during breathing. One factor that determines blood

$$\text{pH} = \frac{\text{Kidney function} = \text{Bicarbonate levels}}{\text{Lung function} = \text{Carbon dioxide levels}}$$

(Slow but powerful response) (Rapid but limited response)

FIG. 14-10 Contribution of pH balance by kidney and lung function.

pH is how much CO₂ is produced by body cells during metabolism versus how rapidly that CO₂ is removed by breathing. Protein breakdown forms sulfuric acid. Fat breakdown forms fatty acids and ketoacids.

Incomplete breakdown of glucose, which occurs whenever cells metabolize under **anaerobic** (no oxygen) conditions, forms lactic acid. Anaerobic conditions occur with hypoxia, sepsis, and shock. Incomplete breakdown of fatty acids, occurring when large amounts of fatty acids are being metabolized, forms ketoacids.

Destruction of cells allows cell contents to be released. Some cell structures (e.g., lysosomes) contain acids. When these acids are released into the extracellular fluid (ECF), free hydrogen ions are dissociated.

Bicarbonate, a weak base, is the main buffer of the ECF. It comes from the intestinal absorption of ingested bicarbonate, pancreatic production of bicarbonate, movement of cellular bicarbonate into the ECF, kidney reabsorption of filtered bicarbonate, and the breakdown of carbonic acid. Once bicarbonate is in the ECF, it is kept at a level 20 times greater than that of carbonic acid.

ACID-BASE REGULATORY ACTIONS AND MECHANISMS

As long as body cells are healthy, they continuously produce acids, carbon dioxide, and free hydrogen ions. Despite this production, hydrogen ion, bicarbonate, oxygen, and carbon dioxide levels are kept within normal limits when acid-base controlling actions/mechanisms are normal. Chart 14-1 lists normal values for these substances in arterial and venous blood. This homeostasis depends on:

TABLE 14-1 ACID-BASE REGULATORY MECHANISMS

MECHANISM TYPE	KEY CHARACTERISTICS
Chemical	
Protein buffers (albumin, globulins, hemoglobin)	Very rapid response
Chemical buffers (bicarbonate, phosphate)	Provide immediate response to changing conditions
	Can handle relatively small fluctuations in hydrogen ion production and elimination encountered under normal metabolic and health conditions
Respiratory	
Increased hydrogen ions or increased carbon dioxide	Primarily assist buffering systems when the fluctuation of hydrogen ion concentration is acute
Stimulates central respiratory neurons, leading to increased rate and depth of breathing, causing more carbon dioxide to be lost and decreasing the hydrogen ion concentration	
Decreased hydrogen ions or decreased carbon dioxide	
Inhibits central respiratory neurons, leading to decreased rate and depth of breathing, causing normally produced carbon dioxide to be retained, increasing the hydrogen ion concentration	
Kidney	
Actions to decrease pH	The most powerful regulator of acid-base balance
Increased kidney excretion of bicarbonate	Respond to large or chronic fluctuations in hydrogen ion production or elimination
Increased kidney reabsorption of hydrogen ions	Slowest response (hours to days)
Actions to increase pH	Longest duration
Decreased kidney excretion of bicarbonate	
Decreased kidney reabsorption of hydrogen ions	

- Hydrogen ion production being consistent and not excessive
- CO₂ loss from the body through breathing keeping pace with all forms of hydrogen ion production

To keep the free hydrogen ion level (pH) of the ECF within the narrow range of normal, the body has chemical, respiratory, and kidney actions (mechanisms) for acid-base balance (Table 14-1).

Chemical Acid-Base Control Actions and Mechanisms

Buffers are the first line of defense against changes in the amount of free hydrogen ions. Because they are always present in body fluids, buffers act fast to reduce or raise the amount of free hydrogen ions to normal. By acting as hydrogen ion “sponges,” buffers can bind hydrogen ions when too many are present or release hydrogen ions when not enough are present. Buffers are composed of chemicals or proteins.

Chemical buffers are paired mixtures—usually a weak base and an acid salt. The two most common chemical buffers are bicarbonate (which is active in both the extracellular fluid [ECF] and intracellular fluid [ICF]) and phosphate (which is active in the ICF).

Protein buffers are the most common buffers. Proteins in body fluids can either bind or release free hydrogen ions as needed. Both ICF and ECF proteins serve as buffers. Extracellular protein buffers are albumin and globulins. A major cell protein buffer is hemoglobin. Hemoglobin buffers hydrogen ions directly and also buffers acids formed during the production of carbon dioxide. When the amount of free hydrogen ions in the blood increases, some of the excess hydrogen ions cross the membranes of red blood cells and bind to the large numbers of hemoglobin molecules in each red blood cell. This binding of hydrogen ions to hemoglobin results in fewer hydrogen ions remaining in the blood, bringing blood pH back up toward normal.

Respiratory Acid-Base Control Actions and Mechanisms

When chemical buffers alone cannot prevent changes in blood pH, the respiratory system is the second line of defense against changes. Breathing controls the amount of free hydrogen ions by controlling the amount of carbon dioxide (CO₂) in arterial blood. Remember, because CO₂ is converted into hydrogen ions through the carbonic anhydrase reaction, the CO₂ level is *directly* related to the hydrogen ion level. Breathing rids the body of the excess CO₂ created through metabolism.

The amount of CO₂ in venous blood increases during normal metabolism. This CO₂ is moved in the blood to the lung capillaries. Because the amount (pressure) of CO₂ is far higher in capillary blood than in the air in the alveoli, CO₂ diffuses freely from the blood into the alveolar air. Once in the alveoli, CO₂ is exhaled during breathing and is lost from the body. Because the amount (pressure) of CO₂ in atmospheric air is nearly zero, CO₂ usually continues to be exhaled even when breathing is impaired.

Respiratory regulation of acid-base balance is under the control of the central nervous system (Fig. 14-11). Special receptors in the respiratory areas of the brain are sensitive to changes in the amount of CO₂ in brain tissues. As the amount of CO₂ begins to rise above normal in brain blood and tissues, these central receptors trigger the neurons to increase the rate and depth of breathing (**hyperventilation**). As a result, more CO₂ is exhaled (“blown off”) from the lungs and the amount of CO₂ in the ECF decreases. When the amount of arterial CO₂ returns back down to normal, the rate and depth of breathing return to levels that are normal for the person.

If the amount of ECF free hydrogen ions is too low, then the amount of CO₂ also is too low. Central receptors sense these low CO₂ levels and stop or slow the neuron activity in the respiratory centers of the brain, decreasing the rate and depth of breathing (**hypoventilation**). As a result, less CO₂ is lost through the lungs and more CO₂ is retained in arterial blood. This retention of already-formed CO₂, together with the normal production of CO₂ from metabolism, results in a rapid return of the arterial CO₂ levels (and hydrogen ion levels) back up to normal. When these levels are normal, the rate and depth of breathing also return to normal levels.

FIG. 14-11 Neural regulation of respiration and hydrogen ion concentration. (P_{aCO_2} , Partial pressure of arterial carbon dioxide; H^+ , hydrogen ion.)

The respiratory system's response in acid-base balance is rapid. Changes in the rate and depth of breathing occur within minutes after changes in the hydrogen ion level or CO_2 level of the ECF occur.

Kidney Acid-Base Control Actions and Mechanisms

The kidneys are the third line of defense against wide changes in body fluid pH. Kidney actions are stronger for regulating acid-base balance but take longer than chemical and respiratory actions to completely respond. (They take 24 to 48 hours to respond.) When blood pH changes are persistent, kidney actions that increase excretion and reabsorption rates of acids or bases (depending on the direction of the pH changes) begin to operate. These actions are kidney movement of bicarbonate, formation of acids, and formation of ammonium.

Kidney movement of bicarbonate is the first kidney pH control action. It occurs in the kidney tubules in two ways: (1) kidney movement of bicarbonate produced elsewhere in the body and (2) kidney movement of bicarbonate produced in the kidneys. Much of the bicarbonate made in other body areas is excreted in the urine. When blood hydrogen ion levels are high, this bicarbonate is reabsorbed from the kidneys back into circulation, where it can help buffer excess hydrogen ions. In this situation, the kidney tubules also can make additional bicarbonate and reabsorb it for an increased buffer effect. When blood hydrogen ion levels are low, the bicarbonate remains in the urine and is excreted.

Formation of acids is the second kidney pH control action. It occurs through the phosphate-buffering system inside the cells of the kidney tubules. When the newly created

bicarbonate made in the kidney cells is reabsorbed into the blood along with sodium, the urine has an excess of anions, including phosphate (HPO_4^{2-}). This negatively charged fluid draws hydrogen ions (which carry a positive charge) into the urine. Once the hydrogen ion is in the urine, it binds to phosphate ions, forming an acid, H_2PO_4 , which is then excreted in the urine.

Formation of ammonium is the third kidney pH control action. Ammonia (NH_3), which is formed during normal protein breakdown, is converted into ammonium (NH_4^+). The ammonia is first secreted into the urine, where it can combine with excess hydrogen ions to form ammonium. The ammonium "traps" the hydrogen ions and then allows them to be excreted in the urine. The result is a loss of hydrogen ions and an increase in blood pH.

Compensation

In the process of *compensation*, the body adapts to attempt to correct changes in blood pH. A pH below 6.9 or above 7.8 is usually fatal. The normal pH range for human extracellular fluid (ECF) is 7.35 to 7.45. Both the kidneys and the lungs can compensate for acid-base imbalances, but they are not equal in their final responses. The respiratory system is much more sensitive to acid-base changes and can begin compensation efforts within seconds to minutes after a change in pH. However, these efforts are limited and can be overwhelmed easily. The kidney compensatory actions are much more powerful and result in rapid changes in ECF composition. However, these more powerful actions are not fully triggered unless the acid-base imbalance continues for several hours to several days.

Respiratory compensation occurs through the lungs, usually to correct for acid-base imbalances from metabolic problems. For example, when prolonged running causes buildup of lactic acid, hydrogen ion levels in the ECF increase and the pH drops. To bring the pH back to normal, breathing is triggered in response to increased carbon dioxide levels. Both the rate and depth of respiration increase. These respiratory efforts cause the blood to lose carbon dioxide with each exhalation, so ECF levels of carbon dioxide and free hydrogen ions gradually decrease. When the lungs can *fully compensate*, the pH returns to normal.

Kidney compensation results when a healthy kidney works to correct for changes in blood pH that occur when the respiratory system either is overwhelmed or is not healthy. For example, in a person with chronic obstructive pulmonary disease (COPD), the respiratory system cannot exchange gases adequately. Carbon dioxide is retained continuously, hydrogen ion levels increase, and the blood pH falls (becomes more acidic). To oppose this process, the kidney excretes more hydrogen ions and increases the reabsorption of bicarbonate back into the blood. As a result, the blood pH remains either within or closer to the normal range. When these backup actions are completely effective, acid-base problems are *fully compensated* and the pH of the blood returns to normal even though the levels of oxygen and bicarbonate may be abnormal.

Sometimes, however, the respiratory problem causing the acid-base imbalance is so severe that kidney actions can only *partially compensate* and the pH is not quite normal. Partial compensation is helpful because it prevents the acid-base imbalance from becoming severe or life threatening.

ACID-BASE IMBALANCES

Acid-base imbalances are changes in the blood hydrogen ion level or pH. These changes are caused by problems with the acid-base regulatory actions and mechanisms of the body or by exposure to dangerous conditions. Imbalances in which blood pH is below normal reflect **acidosis**, and imbalances in which blood pH is above normal reflect **alkalosis**. Acid-base imbalances impair the function of many organs and can be life threatening.

ACIDOSIS

Pathophysiology

In acidosis, the acid-base balance of the blood and other extracellular fluid (ECF) is upset by an excess of hydrogen ions (H^+). This problem is reflected as an arterial blood pH below 7.35. The amount or strength (or both) of acids is greater than normal compared with the amount or strength of bases.

Acidosis is not a disease; it is a condition caused by a disorder or pathologic process. Acidosis can be caused by metabolic problems, respiratory problems, or both. Patients at greatest risk for acute acidosis are those with problems that impair breathing. Older adults with chronic health problems are at greater risk for developing acidosis (Chart 14-2).

CHART 14-2 NURSING FOCUS ON THE OLDER ADULT

The Older Patient Experiencing Acid-Base Imbalance

When Obtaining a Patient's History

- Assess risk factors for acid-base imbalance, including drugs, chronic health problems (especially kidney disease, pulmonary disease), and acute health problems.
- Obtain the history when the patient is awake and more familiar with his or her surroundings.
- Ask the patient to list all prescribed and over-the-counter drugs (especially diuretics and antacids). If he or she cannot recall this information or seems confused, ask the significant other to bring drugs from home to show the nurse.
- Ask the patient to recall what liquids he or she has taken in the past 24 hours and whether he or she has urinated as much as usual.

When Assessing the Patient

- Compare the patient's mental status with what the family, significant other, or health record states is the patient's baseline.
- Observe the rate and depth of respiration.
 - Can the patient complete a sentence without stopping to take a breath?
- Examine the color of the patient's nail beds and mucous membranes.
- Obtain a urine specimen, and observe for color and character. Test for specific gravity and pH.
- Examine skin turgor for dehydration. Attempt to pinch the skin to form a tent over the sternum and on the forehead. If a tent forms, record how long it remains.
- Measure the rate and quality of the pulse.
- Observe the patient's clinical responses and laboratory values carefully while the acid-base imbalance is being corrected.
- Administer IV therapy by pump or controller.

Acidosis can result from an actual or relative increase in the amount or strength of acids. An *actual acid excess* results in acidosis by either overproducing acids (and release of hydrogen ions) or undereliminating normally produced acids (retention of hydrogen ions). Either way, more hydrogen ions are present than should be. Examples of problems that actually increase acid production are diabetic ketoacidosis and seizures. Examples of problems that actually decrease acid elimination are respiratory impairment and kidney impairment.

In *relative acidosis*, the amount or strength of acids does not increase. Instead, the amount or strength (or both) of the bases decreases (to create a *base deficit*), which makes the fluid relatively more acidic than basic. A relative acidosis (*base deficit*) is caused by either overeliminating bases (bicarbonate ions [HCO_3^-]) or underproducing bases (see Fig. 14-4). Examples of problems that underproduce bases are pancreatitis and dehydration. A condition that overeliminates bases is diarrhea.

Regardless of its cause or type, acidosis causes major changes in body function. The main problems are related to the fact that hydrogen ions are positively charged ions. An increase in hydrogen ions creates imbalances of other positively charged electrolytes, especially potassium. The changes in potassium levels because of excess hydrogen ions is described on p. 205 in the Laboratory Assessment section for acidosis. These electrolyte imbalances then disrupt the functions of nerves, cardiac muscle, and skeletal muscle. The early manifestations of acidosis first appear in the musculoskeletal, cardiac, respiratory, and central nervous systems. Even slight increases in blood hydrogen ion levels reduce the activity of many hormones and enzymes, leading to death. Many drugs are less effective during acidosis.

Acidosis can be caused by metabolic problems, respiratory problems, or combined metabolic and respiratory problems. Specific causes of acidosis are listed in Table 14-2.

Metabolic Acidosis

Four processes can result in metabolic acidosis: overproduction of hydrogen ions, underelimination of hydrogen ions, underproduction of bicarbonate ions, and overelimination of bicarbonate ions.

Overproduction of hydrogen ions can occur with excessive breakdown of fatty acids, anaerobic glucose breakdown (*lactic acidosis*), and excessive intake of acids. Excessive breakdown of fatty acids occurs with diabetic ketoacidosis or starvation. When insufficient glucose is available for fuel, the body breaks down fats (lipids). The products of excessive fatty acid breakdown are strong acids (*ketoacids*), which release large amounts of hydrogen ions.

Lactic acidosis occurs when cells are forced to use glucose without adequate oxygen (*anaerobic metabolism*); as a result, glucose is incompletely broken down and forms lactic acid. Lactic acid leaves the cell, enters the blood, and releases hydrogen ions, causing acidosis. Lactic acidosis occurs whenever the body has too little oxygen to meet metabolic oxygen demands, such as during heavy exercise, seizure activity, fever, and reduced oxygen intake.

Excessive intake of acids floods the body with hydrogen ions. Agents that cause acidosis when ingested in excess include alcoholic beverages, methyl alcohol, and acetylsalicylic acid (aspirin).

Underelimination of hydrogen ions leads to acidosis when hydrogen ions are produced at the normal rate but are not removed at the same rate they are produced. Most hydrogen ion loss occurs through the lungs and the kidneys. Kidney failure causes acidosis when the kidney tubules cannot secrete hydrogen ions into the urine. As a result, too many hydrogen ions are retained. Severe lung problems also can result in retention of CO₂, which, because CO₂ concentration is directly related to hydrogen ion levels, means that hydrogen ions are also retained.

Underproduction of bicarbonate ions (base deficit) leads to acidosis when hydrogen ion production and removal are

normal but too few bicarbonate ions are present to balance the hydrogen ions. Such base deficits occur when bicarbonate ions are not produced at the normal rate. Because bicarbonate is made in the kidneys and in the pancreas, kidney failure and impaired liver or pancreatic function can cause a base-deficit acidosis.

Overelimination of bicarbonate ions (base-deficit) leads to acidosis when hydrogen ion production and removal are normal but too many bicarbonate ions have been lost. One cause of base-deficit acidosis is diarrhea.

Respiratory Acidosis

Respiratory acidosis results when any area of respiratory function is impaired, reducing the exchange of oxygen (O₂) and carbon dioxide (CO₂). This problem causes CO₂ retention. Because any increase in CO₂ levels causes the same increase in hydrogen ion levels, CO₂ retention leads to acidosis. (See the carbonic anhydrase equation in Fig. 14-7.)

Unlike metabolic acidosis, respiratory acidosis results from only one cause—retention of CO₂, causing increased production of free hydrogen ions. Four types of respiratory problems lead to overproduction of hydrogen ions: respiratory depression, inadequate chest expansion, airway obstruction, and reduced alveolar-capillary diffusion (see Table 14-2).

Respiratory depression results from depressed function of the brainstem neurons that trigger breathing movements. This reduces the rate and depth of breathing, which leads to poor gas exchange and retention of carbon dioxide. Respiration can be depressed by anesthetic agents, drugs (especially opioids), and poisons such as methyl alcohol, pesticides, and botulinus toxin. Specific electrolyte imbalances also inhibit these neurons (see Chapter 13 for electrolyte imbalances).

Physical depression of respiration occurs when neurons are damaged or destroyed by trauma or when problems in the brain increase the intracranial pressure. This increase causes edema, which presses on the respiratory centers located in the brainstem. Problems causing cerebral edema and respiratory depression include brain tumors, cerebral aneurysm, stroke, and overhydration.

Inadequate chest expansion reduces gas exchange and leads to acidosis. Chest expansion can be restricted by skeletal trauma or deformities, respiratory muscle weakness, or external constriction. Skeletal problems restrict chest wall movement when broken or malformed bones distort the shape of the chest or when the rigidity of the rib cage is lost (*flail chest*). Respiratory muscle weakness, caused by electrolyte imbalances, fatigue, muscular dystrophy, or muscle damage or breakdown reduces chest movement. External conditions also can restrict chest movement and gas exchange. Such conditions include body casts, tight scar tissue around the chest, obesity, and ascites.

Airway obstruction prevents air movement into and out from the lungs (*ventilation*) and leads to poor gas exchange, CO₂ retention, and acidosis. The upper airway can be obstructed externally by clothing, neck edema, and local lymph node enlargement. Internal obstruction of the upper airway can be caused by aspiration of foreign objects, bronchoconstriction, mucus, and edema.

Reduced alveolar-capillary diffusion causes poor gas exchange and leads to CO₂ retention and acidosis. Disorders that reduce diffusion include pneumonia, pneumonitis,

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

The nurse caring for a client who has been NPO for 5 days and receiving only dextrose 5% in lactated Ringer's solution (4 liters daily) reviews the client's most recent arterial blood gas results and observes that the pH is now 7.28. What is the most likely explanation for this finding?

- A. Acidosis in response to the presence of excessive ketoacids
- B. Acidosis in response to the presence of excessive lactic acid
- C. Alkalosis in response to the excessive loss of carbonic acid
- D. Alkalosis in response to the excessive loss of sulfuric acid

TABLE 14-2 COMMON CAUSES OF ACIDOSIS

PATHOLOGY	CONDITION
Metabolic Acidosis	
Overproduction of hydrogen ions	Excessive oxidation of fatty acids Diabetic ketoacidosis Starvation Hypermetabolism Heavy exercise Seizure activity Fever Hypoxia, ischemia Excessive ingestion of acids Ethanol intoxication Methanol ingestion Salicylate intoxication
Underelimination of hydrogen ions	Kidney failure
Underproduction of bicarbonate	Kidney failure Pancreatitis Liver failure Dehydration
Overelimination of bicarbonate	Diarrhea Buffering of organic acids
Respiratory Acidosis	
Underelimination of hydrogen ions	Respiratory depression Anesthetics Drugs (especially opioids) Electrolyte imbalance Head or neck trauma Inadequate chest expansion Skeletal deformities Muscle weakness Nonpulmonary restriction Obesity, casts, eschar Airway obstruction Alveolar-capillary block

tuberculosis, emphysema, acute respiratory distress syndrome, chest trauma, pulmonary emboli, pulmonary edema, and drowning. Cigarette smoking worsens gas exchange and leads to disorders that contribute to respiratory acidosis. Encourage any patient who has respiratory problems to stop smoking.

Combined Metabolic and Respiratory Acidosis

Metabolic and respiratory acidosis can occur at the same time. Uncorrected acute respiratory acidosis always leads to poor oxygenation and lactic acidosis (McCance et al., 2010). For example, a person who has diabetic ketoacidosis and chronic obstructive pulmonary disease has a combined metabolic and respiratory acidosis. Combined acidosis is more severe than either metabolic acidosis or respiratory acidosis alone.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

History

Collect data about risk factors related to the development of acidosis, specifically age, nutrition, and presenting symptoms. One way of organizing data to assess acid-base status is to use Gordon's Functional Health Patterns, especially Activity-Exercise, Elimination, and the Cognitive-Perceptual patterns (Chart 14-3).

CHART 14-3 ACID-BASE ASSESSMENT

Using Gordon's Functional Health Patterns

Activity-Exercise Pattern

- Have you had any shortness of breath or difficulty breathing at rest or during activity?
- Have you noticed any changes in your breathing rate or depth?
- Do you have a hard time "catching" your breath?
- Do you have any difficulty clearing excretions?
- Do you feel the need for additional energy to accomplish routine tasks?
- Do you have any difficulty concentrating?
- Have you noticed any changes in your interest in normal daily activities?
- Have you noticed any changes in your leisure activities?

Elimination Pattern

- What is your usual urinary elimination pattern? Frequency? Amount? Color? Odor? Control?
- Have you noticed any changes in the amount of urine?
- Has your urine changed color or odor?
- What is your usual bowel elimination pattern? Frequency? Amount? Control?
- Have you noticed any changes in the number or consistency of your stools?

Cognitive-Perceptual Pattern

- Have you noticed any changes in memory lately?
- Have you noticed an increase in anxiety or feelings of apprehension?
- Are you sleeping more or sleeping less than usual for you?
- Have you noticed any changes in your attention span?
- Have your muscles seemed weak or "twitchy" lately?

Based on Gordon, M. (2010). *Manual of nursing diagnosis* (12th ed.). Boston: Jones & Bartlett.

Older adults are more at risk for problems leading to acid-base imbalance, including cardiac, kidney, or pulmonary impairment. In addition, older adults are more likely to be taking drugs that disrupt acid-base, fluid, and electrolyte balance, especially diuretics and aspirin. Ask about specific risk factors, such as any type of breathing problem, kidney failure, diabetes mellitus, diarrhea, pancreatitis, and fever.

Obtain a detailed nutrition history to determine total caloric intake and the proportions of carbohydrates, fats, and proteins ingested. Ask whether the patient has fasted or followed a strict diet within the past week.

Ask about headaches, behavior changes, increased drowsiness, reduced alertness, reduced attention span, lethargy, anorexia, abdominal distention, nausea or vomiting, muscle weakness, or increased fatigue. Having the patient relate activities of the previous 24 hours may help identify activity intolerance, behavior changes, and unexplained fatigue. Because the central nervous system is often depressed in acidosis, you may need to obtain this information from the patient's family.

Physical Assessment/Clinical Manifestations

Manifestations of acidosis are similar whether the cause is metabolic or respiratory (Chart 14-4). Acidosis reduces the ability of excitable membranes to respond appropriately, especially in cardiovascular tissue, neurons, skeletal muscle, and GI smooth muscle.

Cardiovascular changes are first seen with mild acidosis and are more severe as the condition worsens. Early changes include increased heart rate and cardiac output. With worsening acidosis or with acidosis and **hyperkalemia** (elevated blood potassium levels), heart rate decreases, T waves become tall and peaked, and QRS complexes are widened. Peripheral pulses may be hard to find and are easily blocked. Hypotension may occur as a result of vasodilation.

CHART 14-4 KEY FEATURES

Acidosis

Cardiovascular Manifestations

- Delayed electrical conduction:
 - Ranges from bradycardia to heart block
 - Tall T waves
 - Widened QRS complex
 - Prolonged PR interval
- Hypotension
- Thready peripheral pulses

Central Nervous System Manifestations

- Depressed activity (lethargy, confusion, stupor, coma)

Neuromuscular Manifestations

- Hyporeflexia
- Skeletal muscle weakness
- Flaccid paralysis

Respiratory Manifestations

- Kussmaul respirations (in metabolic acidosis with respiratory compensation)
- Variable respirations (generally ineffective in respiratory acidosis)

Integumentary Manifestations

- Warm, flushed, dry skin in metabolic acidosis
- Pale to cyanotic and dry skin in respiratory acidosis

! NURSING SAFETY PRIORITY**Critical Rescue**

Assess the cardiovascular system first in any patient at risk for acidosis.

Central nervous system (CNS) changes include depression of CNS function. Problems may range from lethargy to confusion, especially in older patients. As acidosis worsens, the patient may become unresponsive. Assess the patient's mental status (see [Chapter 43](#)).

Neuromuscular changes with acidosis include reduced muscle tone and deep tendon reflexes. The cause of these changes is hyperkalemia along with acidosis. Assess muscle strength in several ways, including arm muscle strength and leg muscle strength. Test arm muscle strength first by having the patient squeeze your hand. Another way to test arm muscle strength is to have the patient flex his or her arms against the chest and keep them flexed while you attempt to pull the arms away from the chest. Test leg muscle strength by having the patient push both feet against a flat surface (like a box or a board) while you apply resistance to the opposite side of the flat surface. This muscle weakness is bilateral and can progress to paralysis.

Respiratory changes may cause the acidosis and can be caused by the acidosis. Assess the patient's rate, depth, and ease of breathing. Use pulse oximetry to determine how well oxygen is delivered to the peripheral tissues.

If acidosis is metabolic in origin, the rate and depth of breathing increase as the hydrogen ion level rises. Breaths are deep and rapid and not under voluntary control. This breathing pattern is called **Kussmaul respiration**.

If acidosis is caused by respiratory problems, breathing efforts are reduced. Respirations are usually shallow and rapid. Muscle weakness makes this problem worse.

Skin changes occur with metabolic or respiratory acidosis. With metabolic acidosis, breathing is unimpaired and the rate is increased and CO_2 is lost. This causes vasodilation and makes the skin and mucous membranes warm, dry, and pink. With respiratory acidosis, breathing is ineffective and skin and mucous membranes are pale to cyanotic.

Psychosocial Assessment

It is vital to complete a psychosocial assessment, because behavioral changes may be the first manifestations of acidosis. Observe and document the patient's behavior by description

(objectively) rather than by interpretation (subjectively). For example, you should state that "the patient does not recognize close family members" rather than "the patient is confused." Ask family members if the patient's behavior is typical for him or her, and establish a baseline for comparison with later assessment findings.

Laboratory Assessment

Arterial blood pH is the laboratory value used to confirm acidosis. Acidosis is present when arterial blood pH is less than 7.35. However, this test alone does not indicate what is causing the acidosis. Manifestations of metabolic acidosis and respiratory acidosis are similar, but their treatments are different. *Therefore it is critical to obtain and interpret other laboratory data, such as arterial blood gas (ABG) values and blood levels of electrolytes (Chart 14-5).*

Metabolic acidosis is reflected by several changes in ABG values. The pH is low (<7.35) because buffering and respiratory compensation are not adequate to keep the amount of free hydrogen ions at a normal level. The bicarbonate level is low (<21 mEq/L). It is low because (1) bicarbonate has been lost, causing a base-deficit acidosis; (2) bicarbonate production is inadequate, causing a base-deficit acidosis; or (3) bicarbonate may be bound to other substances. The partial pressure of arterial oxygen (PaO_2) is normal because gas exchange is not impaired. The partial pressure of arterial carbon dioxide (PaCO_2) is normal or even slightly decreased because gas exchange is adequate and carbon dioxide retention is not a factor.

The serum potassium level is often high in acidosis as the body attempts to maintain electroneutrality during buffering. [Fig. 14-12](#) shows the movement of potassium ions as serum pH changes. As the blood hydrogen ion level rises, some of the excess hydrogen ions enter red blood cells for intracellular buffering. The movement of hydrogen ions into the cells creates an excess of positive ions inside the cells. To balance these extra positive charges, an equal number of potassium ions (that also have a positive charge) move from the cells into the blood. This increases the blood potassium level, causing hyperkalemia.

Respiratory acidosis is reflected by several changes in ABG values. The pH is low (<7.35) because of the increased amount of free hydrogen ions in the blood. Buffering and kidney compensation are not adequate to keep the amount of free hydrogen ions at a normal level. If the kidneys partially compensate for this acidosis, pH is low but not as abnormal as could be expected with the degree of CO_2 retention.

CHART 14-5 LABORATORY PROFILE**Acid-Base Imbalances (Uncompensated)**

IMBALANCE	LABORATORY VALUE CHANGES						
	pH	HCO_3^-	PaO_2	PaCO_2	K^+	Ca^{2+}	Cl^-
Metabolic acidosis	↓	↓	Ø	Ø and ↓	↑	Ø	Ø and ↑
Respiratory acidosis	↓	Ø	↓	↑	↑	Ø	↑ ↓
Combined acidosis	↓	↓ ↑	↓	↑	↑	Ø	↑
Metabolic alkalosis	↑	↑	Ø	Ø and ↑	↓	↓	↓
Respiratory alkalosis	↑	Ø	Ø	↓↓	↓	↓	↑
Combined alkalosis	↑	↑	Ø	↓	↓	↓	↓

↑, Above normal; ↓, below normal; ↑ ↓, value can increase or decrease depending on other factors; Ø, normal; Ca^{2+} , calcium ions; Cl^- , chloride ions; PaCO_2 , partial pressure of arterial carbon dioxide; PaO_2 , partial pressure of arterial oxygen; HCO_3^- , bicarbonate ions; K^+ , potassium ions.

FIG. 14-12 Movement of potassium (K^+) in response to changes in the extracellular fluid hydrogen ion (H^+) concentration.

The partial pressure of arterial oxygen (P_{aO_2}) is low and the partial pressure of arterial carbon dioxide (P_{aCO_2}) is high because the pulmonary problem impairs gas exchange, causing poor oxygenation and CO_2 retention. (*The hallmarks of respiratory acidosis are a decreasing P_{aO_2} coupled with a rising P_{aCO_2} .*) Carbon dioxide is 20 times more able than oxygen to diffuse across the alveolar membrane. Therefore a decreased P_{aO_2} usually occurs before an increased P_{aCO_2} .

The serum bicarbonate level is variable. A patient with rapid onset of respiratory acidosis often has a normal bicarbonate level because kidney compensation has not started. When respiratory acidosis persists for 24 hours or longer, kidney compensation increases the levels of bicarbonate. Chronic respiratory acidosis is indicated by an elevated bicarbonate level and increased P_{aCO_2} .

Serum potassium levels are elevated in acute respiratory acidosis. They are normal or low in chronic respiratory acidosis when kidney compensation is present.

Priority Patient Problems

Priority problems for the patient experiencing acidosis are associated with the decreased function of excitable membranes. These problems include hypotension and decreased perfusion, impaired memory and cognition, and increased risk for falls.

INTERVENTIONS

Interventions for acidosis focus on correcting the underlying problem and monitoring for changes. To ensure appropriate interventions, the specific type of acidosis must first be identified.

Metabolic Acidosis

Interventions for metabolic acidosis include hydration and drugs or treatments to control the problem causing the

acidosis. For example, if the acidosis is a result of diabetic ketoacidosis, insulin is given to correct the hyperglycemia and halt the production of ketone bodies. Rehydration and antidiarrheal drugs are given if the acidosis is a result of prolonged diarrhea. Bicarbonate is administered only if serum bicarbonate levels are low.

Nursing priorities include continuously monitoring the patient for changes that indicate either he or she is responding to the treatment or the acidosis is becoming worse. The cardiovascular system and the skeletal muscle system are sensitive to acidosis and are the most important systems to monitor. Interpreting ABG results is an important part of monitoring.

Respiratory Acidosis

Priority interventions for respiratory acidosis are focused on improving ventilation and oxygenation and maintaining a patent airway. These include drug therapy, oxygen therapy, pulmonary hygiene (positioning and breathing techniques), ventilatory support, and prevention of complications. (See Chapter 32 for disorders causing respiratory acidosis.)

Drug therapy is focused on improving ventilation and oxygenation rather than directly on altering arterial pH. The major categories of drugs useful for respiratory problems that lead to acidosis include bronchodilators, anti-inflammatories, and mucolytics.

Oxygen therapy helps promote gas exchange for patients with respiratory acidosis. However, use caution when giving oxygen to patients with chronic obstructive pulmonary disease (COPD) and CO_2 retention as evidenced by a high P_{aCO_2} level. The only breathing trigger for these patients is a decreased arterial oxygen level. *Giving too much oxygen to these patients decreases their respiratory drive and may lead to respiratory arrest.*

! NURSING SAFETY PRIORITY**Critical Rescue**

When administering oxygen therapy to the patient with COPD and CO₂ retention who is not being artificially ventilated, assess respiratory effort and effectiveness hourly. Report a respiratory rate consistently lower than 10 breaths per minute to the Rapid Response Team.

Ventilation support with mechanical ventilation may be needed for patients who cannot keep their oxygen saturation at 90% or who have respiratory muscle fatigue. Chapter 34 discusses the nursing care needs of patients who are being mechanically ventilated.

Preventing complications is a nursing priority when caring for a patient with respiratory acidosis. Monitoring breathing status and intervening when changes occur are critical in preventing complications. For patients who have chronic respiratory acidosis, assess breathing status at least every 2 hours. Listen to breath sounds, and assess how easily air moves into and out of the lungs. Check for any muscle retractions, the use of accessory muscles (especially the neck muscles [sternocleidomastoids]), and whether breathing produces a sound (like a grunt or a wheeze) that can be heard without a stethoscope. Assess the color of the nail beds and oral membranes for cyanosis (a late finding).

ALKALOSIS**Pathophysiology**

In patients with alkalosis, the acid-base balance of the blood is disturbed and has an excess of bases, especially bicarbonate (HCO₃⁻). The amount or strength (or both) of the bases is greater than normal compared with the amount or strength of the acids. Alkalosis is a *decrease* in the free hydrogen ion level of the blood and is reflected by an arterial blood pH *above* 7.45. Like acidosis, alkalosis is not a disease but, rather, a manifestation of a problem. Alkalosis can be caused by metabolic problems, respiratory problems, or both (Table 14-3).

Alkalosis can result from an actual or relative increase in the amount or strength (or both) of bases. In an actual base excess, alkalosis occurs when base (usually bicarbonate) is either overproduced or undereliminated.

In *relative* alkalosis, the actual amount or strength of bases does not increase. Instead, the amount or strength (or both) of the acids decreases, creating an *acid deficit* and making the blood more basic than acidic. A relative base-excess alkalosis (acid deficit) results from an overelimination or underproduction of acids (Fig. 14-13).

The problems of alkalosis are serious and potentially life threatening. Management focuses on correcting the cause of alkalosis after identifying whether it is respiratory or metabolic in origin.

Whether metabolic, respiratory, or both, alkalosis affects specific functions. The pathologic effects are caused by the electrolyte imbalances that occur in response to decreased blood cation (positively charged particles) levels. Most problems of alkalosis are related to increased stimulation of the nervous, neuromuscular, and cardiac systems.

Metabolic alkalosis is caused by any condition that creates the acid-base imbalance through either an increase of bases

TABLE 14-3 COMMON CAUSES OF ALKALOSIS

PATHOLOGY	CONDITION
Metabolic Alkalosis	
Increase of base components	Oral ingestion of bases Antacids Milk-alkali syndrome Parenteral base administration Blood transfusion Sodium bicarbonate Total parenteral nutrition
Decrease of acid components	Prolonged vomiting Nasogastric suctioning Hypocortisolism Hyperaldosteronism Thiazide diuretics
Respiratory Alkalosis	
Excessive loss of carbon dioxide	Hyperventilation Fear, anxiety Mechanical ventilation Salicylate toxicity Hypoxemia-stimulated hyperventilation High altitudes Shock Early-stage acute pulmonary problems

(base excess) or a decrease of acids (acid deficit). Base excesses are caused by excessive intake of bicarbonates, carbonates, acetates, and citrates. Excessive use of oral antacids containing sodium bicarbonate or calcium carbonate can also cause a metabolic alkalosis. Other base excesses can occur during medical treatments, such as citrate excesses during massive blood transfusions and IV sodium bicarbonate given to correct acidosis. The hallmark of a base-excess alkalosis is an ABG result with an elevated pH and an elevated bicarbonate level along with normal oxygen and carbon dioxide levels.

Acid deficits can be caused by disease processes or medical treatment. Disorders causing acid deficits include prolonged vomiting, excess cortisol, and hyperaldosteronism. Medical treatments that promote acid loss causing metabolic alkalosis include thiazide diuretics and prolonged gastric suctioning.

Respiratory alkalosis is usually caused by an excessive loss of CO₂ through hyperventilation (rapid respirations). Patients may hyperventilate in response to anxiety, fear, or improper settings on mechanical ventilators. Hyperventilation can also result from direct stimulation of central respiratory centers because of fever, central nervous system lesions, and salicylates. The hallmark of respiratory alkalosis is an ABG result with an elevated pH coupled with a low carbon dioxide level. Usually, the oxygen and bicarbonate levels are normal.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Manifestations are the same for metabolic and respiratory alkalosis. Many symptoms are the result of the low calcium levels (**hypocalcemia**) and low potassium levels (**hypokalemia**) that usually occur with alkalosis (see Fig. 14-12). These problems change the function of the nervous, neuromuscular, cardiac, and respiratory systems (Chart 14-6).

Central nervous system (CNS) changes are caused by over-excitement of the nervous systems. Patients have dizziness, agitation, confusion, and hyperreflexia, which may progress to seizure activity. Tingling or numbness around the mouth and in the toes may be present. Other indicators of alkalosis with hypocalcemia are positive Chvostek's and Trousseau's signs (see Chapter 13).

Neuromuscular changes are related to the hypocalcemia and hypokalemia that occur with alkalosis. Hypocalcemia increases nervous system activity, causing muscle cramps, twitches, and "charley horses." Deep tendon reflexes are hyperactive. **Tetany** (continuous contractions) of muscle groups also may be present. Tetany is painful and indicates a rapidly worsening condition.

Skeletal muscles may contract as a result of nerve over-stimulation, but they become weaker because of the hypokalemia. Handgrip strength decreases, and the patient may be unable to stand or walk. Respiratory efforts become less effective as the skeletal muscles of respiration weaken.

Cardiovascular changes occur because alkalosis increases myocardial irritability, especially when accompanied by hypokalemia. Heart rate increases, and the pulse is thready. When hypovolemia (decreased blood volume) is also present, the patient may have severe hypotension. The hypokalemia increases myocardial sensitivity to digoxin, which increases the risk for digoxin toxicity.

Respiratory changes, especially increases in the rate of breathing, are the main causes of respiratory alkalosis.

Although the volume of air inhaled and exhaled with each breath is nearly normal, the total volume of air inhaled and exhaled each minute rises with the increased respiratory rate. The increased minute volume may be caused by anxiety or physiologic changes.

Arterial blood pH greater than 7.45 confirms alkalosis, but this test alone does not identify its cause. Because the manifestations of metabolic alkalosis and respiratory alkalosis are similar, it is critical to obtain additional laboratory data, especially arterial blood gas (ABG) values and specific serum electrolyte levels (see Chart 14-5).

INTERVENTIONS

Interventions are planned to prevent further losses of hydrogen, potassium, calcium, and chloride ions; to restore fluid balance; to monitor changes; and to provide for *patient safety*. Treatments that may have caused alkalosis (e.g., prolonged gastric suctioning, excessive infusion of IV solutions containing bases, drugs that promote hydrogen ion excretion) are modified or stopped. Drug therapy is used for alkalosis. Drugs are prescribed to resolve the causes of alkalosis and to restore normal fluid, electrolyte, and acid-base balance. For example, the patient with metabolic alkalosis caused by diuretic therapy receives fluid and electrolyte replacement, and the diuretic therapy is stopped, at least temporarily. Antiemetic drugs are prescribed if the cause of alkalosis is vomiting. Fluids and electrolytes are replaced orally or parenterally. Carefully monitor the patient's progress, and adjust fluid and electrolyte therapy. Serum electrolyte values are monitored daily until they return to normal or near normal.

During correction of alkalosis, a nursing care priority is prevention of injury caused by falls. The patient with alkalosis has hypotension and muscle weakness, both of which increase the risk for falls, especially among older adults. Implement the general falls prevention nursing interventions and the high-risk falls prevention nursing interventions outlined in Chart 3-4 in Chapter 3.

CHART 14-6 KEY FEATURES

Alkalosis

Central Nervous System Manifestations

- Increased activity
- Anxiety, irritability, tetany, seizures
- Positive Chvostek's sign
- Positive Trousseau's sign
- Paresthesias

Neuromuscular Manifestations

- Hyperreflexia
- Muscle cramping and twitching
- Skeletal muscle weakness

Cardiovascular Manifestations

- Increased heart rate
- Normal or low blood pressure
- Increased digitalis toxicity

Respiratory Manifestations

- Increased rate and depth of ventilation in respiratory alkalosis
- Decreased respiratory effort associated with skeletal muscle weakness in metabolic alkalosis

DECISION-MAKING CHALLENGE

Patient-Centered Care; Safety

The patient is a 55-year-old salesman who returned from a business trip to Mexico 2 days ago. He started feeling nauseated on the plane trip home and has been vomiting for the past 40 hours. His current arterial blood gas results are pH = 7.49; HCO_3^- = 26 mEq/L; PaCO_2 = 40 mm Hg; PaO_2 = 98 mm Hg. His current therapy includes IV antiemetics and an infusion of dextrose 5% in lactated Ringer's solution at 250 mL/hr. His other health problems include moderate hypertension managed with losartan (Cozaar) 50 mg daily and hydrochlorothiazide (HydroDIURIL) 25 mg daily, benign prostatic hyperplasia managed with tamsulosin (Flomax) 0.4 mg daily, and gastroesophageal reflux disease managed with esomeprazole (Nexium) 10 mg four times daily.

1. What specific type of acid-base problem does this patient have?
2. What is the most probable origin of the acid-base imbalance?
3. Could any of his prescription drugs have contributed to this problem? If so, which one(s) and how?
4. What nursing interventions for safety are most appropriate for this patient?
5. When he stops vomiting, which of these drugs should he receive and which should be withheld? Provide a rationale for your decisions.

GET READY FOR THE NCLEX® EXAMINATION!**KEY POINTS**

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Use caution in giving oxygen to people who have COPD, and monitor their respiratory effort at least hourly.
- Identify patients at increased risk for falls as a result of muscle weakness with acid-base imbalances.

Health Promotion and Maintenance

- Teach all patients to take drugs as prescribed, especially diuretics, antihypertensives, and cardiac drugs.
- Instruct all patients at continuing risk for respiratory acidosis to stop smoking.

Psychosocial Integrity

- Assess the oxygenation status of any patient with acute confusion.
- Monitor the neurologic status at least every 2 hours in patients being treated for an acid-base imbalance.
- Assist patients who have anxiety-induced respiratory alkalosis to identify causes of anxiety.
- Teach patients who have anxiety-induced respiratory alkalosis to use stress management techniques.

Physiological Integrity

- The normal pH of the body's extracellular fluids (including blood) is 7.35 to 7.45.
- The normal pH of arterial blood is slightly higher (less acidic) than venous blood.
- The more hydrogen ions present, the more acidic the fluid.
- The fewer hydrogen ions present, the more alkaline the fluid.
- Lower pH values (below 7.35) mean acidosis is present.
- Higher pH values (above 7.45) mean alkalosis is present.
- The concentration of CO_2 is directly related to the concentration of hydrogen ions.
- Anything that increases the CO_2 level in the blood increases the hydrogen ion content and lowers the pH.
- An acid gives up hydrogen ions in solution; a base binds hydrogen ions in solution.

- Acids are normally formed in the body as a result of metabolism and incomplete breakdown of glucose and fats.
- Acid-base balance is regulated by chemical, respiratory, and kidney actions.
- Chemical buffers are the immediate way that acid-base imbalances are corrected.
- The lungs control the amount of CO_2 that is retained or exhaled.
- The kidneys regulate the amount of hydrogen and bicarbonate ions that are retained or excreted by the body.
- Compensation is the process in which the body uses its three regulatory mechanisms to correct for changes in the pH of body fluids.
- If a lung problem causes retention of carbon dioxide, the healthy kidney compensates by increasing the amount of bicarbonate that is produced and retained.
- The best way to determine acid-base balance is to analyze arterial blood gases (ABGs).
- Check the serum potassium level for any patient who has acidosis.
- Assess heart rate and rhythm at least every 2 hours for any patient with an acid-base imbalance.
- Acidosis reduces the excitability of cardiovascular muscle, neurons, skeletal muscle, and GI smooth muscle.
- Alkalosis increases the sensitivity of excitable tissues allowing them to over-respond to normal stimuli and even respond without stimulation.
- Assess the airway of any patient who has acute respiratory acidosis.
- Monitor arterial blood gas values to evaluate the effectiveness of therapy for acid-base imbalances.
- The hallmark of a base-excess acidosis is an ABG result with an elevated pH and an elevated bicarbonate level along with normal oxygen and carbon dioxide levels.
- The hallmark of respiratory alkalosis is an ABG result with an elevated pH coupled with a low carbon dioxide level.
- Patients who have either acidosis or alkalosis are at risk for falls.

Key Points

Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Prevent IV administration errors by following best practices that ensure patient and staff safety.
2. Explain how emerging technology related to infusion therapy can enhance patient safety.
3. Teach the patient and family about the type and care related to the patient's infusion therapy.
4. Identify the evidence-based recommendations for prevention of intravenous (IV) catheter-related bloodstream infection (CR-BSI).

Health Promotion and Maintenance

5. Describe the special needs and care for older adults receiving IV therapy.

Physiological Integrity

6. Check the accuracy of prescriptions for IV fluids and drug therapy.

7. Identify the appropriate veins for peripheral IV catheter insertion.
8. Differentiate types of vascular access devices (VADs) used for peripheral and central IV therapy.
9. Use best practice for inserting peripheral vascular access devices (VADs).
10. Assess the patient's infusion site frequently for local complications, such as phlebitis and infiltration.
11. Prioritize nursing interventions for maintaining an infusion system.
12. Assess, prevent, and manage systemic complications related to infusion therapy and VADs.
13. Identify nursing care associated with intra-arterial, intraperitoneal, subcutaneous, intraosseous, and intraspinal infusion therapy.

Infusion therapy is the delivery of medications in solution and fluids by parenteral (piercing of skin or mucous membranes) route through a wide variety of catheter types and locations using multiple procedures. IV therapy is the most

common route for infusion therapy. It delivers solutions directly into the veins of the vascular system. This chapter focuses on access for and administration of all types of infusion therapy.

*Acknowledgment to Meredith Baker, BSN, RN, and Angela Tyus, RN, Winchester Medical Center Vascular Access Team nurses and Seth Flickinger, BS Engineering Science and Mechanics, Director of Bio-Medical, Valley Health for their assistance in reviewing this chapter.

OVERVIEW

Infusion therapy is delivered in all health care settings, including hospitals, home care, ambulatory clinics, physicians' offices, and long-term care facilities. The most common reasons for using infusion therapy are to:

- Maintain fluid balance or correct fluid imbalance
- Maintain electrolyte or acid-base balance or correct electrolyte or acid-base imbalance
- Administer medications
- Replace blood or blood products

IV therapy is the most common invasive therapy administered to hospitalized patients. Advances in medicine and technology have made it possible for people with chronic diseases such as diabetes mellitus, chronic kidney disease, and malabsorption syndromes to live long and productive lives. These patients are often dependent on long-term infusion therapy of some kind. They often have very poor vascular integrity and, therefore, accessing their peripheral veins takes a high level of skill.

Having a specialized team of infusion nurses to initiate and maintain infusion therapy is recommended by the Centers for Disease Control and Prevention (CDC) to reduce complications of infusion therapy (O'Grady et al., 2011). These teams have demonstrated value in cost savings, patient satisfaction, and patient outcomes.

Infusion nurses may perform any or all of the following activities:

- Develop evidence-based policies and procedures
- Insert and maintain (sterile dressings and flushing) several types of peripheral and central venous catheters
- Monitor patient outcomes
- Educate staff, patients, and families
- Consult on product selection and purchasing decisions
- Therapies such as blood withdrawal, therapeutic phlebotomy, hypodermoclysis, intraosseous infusions, and administration of medications including chemotherapy

The registered nurse (RN) generalist is taught to insert peripheral IVs, and most institutions have a process of credentialing this skill. Depending on the state's nurse practice act, licensed practical/vocational nurses (LPNs/LVNs) and technicians can be trained and credentialed to perform the skill of peripheral IV insertion and assist with infusions, but the RN is ultimately accountable for all aspects of infusion therapy and delegation of associated tasks (*Infusion Nurses Society [INS], 2006*).

The Infusion Nurses Society (INS) publishes guidelines and standards of practice for policy and procedure development in all health care settings. These standards establish the criteria for all nurses delivering infusion therapy. The Infusion Nurses Certification Corporation (INCC) offers a written certifying examination. Nurses who successfully complete this examination have mastered an advanced body of knowledge in this specialty and may use the initials *CRNI*, which stand for *certified registered nurse infusion*.

Types of Infusion Therapy Fluids

Many types of parenteral fluids are used for infusion therapy. These fluids include:

- IV solutions, including parenteral nutrition
- Blood and blood components
- Drug therapy

Intravenous Solutions

More than 200 IV fluids (solutions) are available that meet the requirements established by the United States

Pharmacopeia (USP). Each solution is classified by its tonicity (concentration) and pH. Tonicity is typically categorized by comparison with normal blood plasma as osmolality (mOsm/L). As discussed in [Chapter 13](#), normal serum osmolality for adults is between 270 and 300 mOsm/L. Parenteral solutions within that normal range are **isotonic**; those fluids greater than 300 mOsm/L are **hypertonic**; and those fluids less than 270 mOsm/L are **hypotonic**. [Table 13-4](#) in [Chapter 13](#) lists common IV solutions according to their tonicity.

When an **isotonic infusate** (solution that is infused into the body) is used, water does not move into or out of the body's cells. Therefore patients receiving isotonic solutions are at risk for fluid overload, especially older adults. This complication is discussed in [Chapter 13](#). **Hypertonic** fluids are used to correct fluid, electrolyte, and acid-base imbalances by moving water out of the body's cells and into the bloodstream. Parenteral nutrition solutions are also hypertonic (see [Chapter 63](#)). Instead of moving water out of cells, **hypotonic** infusates move water into cells to expand them. Patients receiving either hypertonic or hypotonic fluids are at risk for phlebitis and infiltration. **Phlebitis** is the inflammation of a vein caused by mechanical, chemical, or bacterial irritation. **Infiltration** occurs when IV solution leaks into the tissues around the vein.

The pH of IV solutions measures the acidity or alkalinity and usually ranges from 3.5 to 6.2. Extremes of both osmolality and pH can cause vein damage leading to phlebitis and **thrombosis** (blood clot in the vein). Thus fluids and medications with a pH value less than 5 and more than 9 and with an osmolality more than 600 mOsm/L are best infused in the central circulation where greater blood flow provides adequate hemodilution ([Perucca, 2010](#)). For example, total parenteral nutrition (TPN) solutions have an osmolality greater than 1400 mOsm/L. TPN should not be infused in peripheral circulation because it can damage blood cells and the endothelial lining of the veins.

! NURSING SAFETY PRIORITY

Drug Alert

Drugs such as amiodarone (Cordarone), vancomycin (Vancocin), and ciprofloxacin (Cipro I.V.) are venous irritants and have a pH less than 5. Phlebitis occurs when patients require long-term infusion of these drugs in peripheral circulation. Drugs with vasoconstrictive action, such as dopamine, or chemotherapeutic agents, such as vinblastine, are vesicants that can cause extravasation. **Extravasation** results in severe tissue damage as manifested by blistering, tissue sloughing, or necrosis from infiltration into the surrounding tissues (see [Complications of Intravenous Therapy](#) section on p. 227 for further explanation and [Chapter 24](#) for more detail). Monitor the IV insertion site carefully for early manifestations of infiltration, including swelling, coolness, or redness. If any of these symptoms are present, discontinue the drug immediately and notify the infusion therapy team, if available. If an infusion specialist is not available, plan to remove the IV catheter and consider central line placement.

Blood and Blood Components

Blood transfusion is given by using packed red blood cells, created by removing a large portion of the plasma from whole blood. Other available blood components include platelets, fresh frozen plasma, albumin, and several specific clotting factors. Each component has detailed requirements for blood-type compatibility and infusion techniques. For patient safety,

The Joint Commission's 2010 National Patient Safety Goals (NPSGs) require agencies to ensure that blood components are properly ordered, handled and dispensed, and administered and that patients are appropriately monitored. Positive patient identification using two patient identifiers and requiring two qualified health care professionals is essential before any blood or blood component is administered. Most organizations use the International Society of Blood Transfusion (ISBT) universal bar-coding system to ensure the right blood for the right patient (Fig. 15-1). The ISBT system includes four components that must be present on the blood label both in bar code and in eye-readable format. These four components are (1) a unique facility identifier, (2) the lot number relating to the donor, (3) the product code, and (4) the ABO group and Rh type of the donor.

An acute hemolytic transfusion reaction caused by an incompatible blood transfusion is a “sentinel event” requiring an intense analysis of the contributing factors and corrective action. Established policies and procedures must be rigidly followed to ensure a safe transfusion and reduce the risk for complications. (See Chapter 42 for a complete discussion of blood transfusion administration.)

Drug Therapy

IV drugs provide a rapid therapeutic effect but can lead to immediate serious reactions, called **adverse drug events (ADEs)**. Hundreds of drugs are available for infusion by a variety of techniques. As with all drug administration, nurses must be knowledgeable about drug indications, proper dosage, contraindications, and precautions. IV administration also requires knowledge of appropriate dilution, rate of infusion, pH and osmolality, compatibility with other IV medications, appropriate infusion site (peripheral versus central circulation), potential for vesicant/irritant effects, and specific aspects of patient monitoring because of its immediate effect. *Regardless of familiarity with the drug, never assume that IV administration is the same as giving that drug by other routes.* New information is continuously being published, and new drugs are rapidly being introduced.

FIG. 15-1 Unit of blood showing the International Society of Blood Transfusion (ISBT) universal barcode for blood transfusions.

Medication safety is extremely important in all health care settings today. The Joint Commission publishes new and updated National Patient Safety Goals (NPSGs) every year. One major goal is improving the safety of high-alert drugs. An example of these drugs is concentrated electrolyte solutions (e.g., potassium chloride), which require restricted access, prominent warnings about the concentration, and storage in a secured location.

Procedures must be established to prevent errors resulting from look-alike, sound-alike drugs such as Celebrex IV (celecoxib) and Cerebyx (fosphenytoin). Other strategies to reduce errors include limiting available concentrations of drugs and dispensing all drugs, including catheter flush solutions, in single-dose containers. Smart pumps, with drug libraries (see **Infusion Systems** section), in combination with computer physician order entry (CPOE) and barcode medication administration (BCMA) systems, use recent technology to help reduce adverse drug events (ADEs). Electronic medication administration records (MARs) and multiple checks by pharmacists, as required by The Joint Commission's NPSGs, also help reduce errors.

Prescribing Infusion Therapy

A prescription for infusion therapy written by a physician or other authorized health care provider is necessary before IV therapy begins. To be complete, the prescription for infusion fluids should include:

- Specific type of fluid
- Rate of administration written in milliliters per hour, or the total amount of fluid and the total number of hours for infusion (e.g., 125 mL/hr or 1000 mL/8 hr)
- Drugs and the specific dose to be added to the solution, such as electrolytes or vitamins

A drug prescription should include:

- Drug name, preferably by generic name
- Specific dose and route
- Frequency of administration
- Time of administration
- Length of time for infusion
- Purpose (required in some health care agencies, especially nursing homes)

Some continuously infused drugs, such as those for pain management, are prescribed as milligrams per hour. The type and volume of dilution for infusion medications may be included in the prescription or calculated by the infusion pharmacist.

! NURSING SAFETY PRIORITY

Action Alert

Determine that the IV prescription is appropriate for the patient and clarify any questions with the health care provider before administration. Be sure to check for the accuracy and completeness of the treatment prescription. An example of an incomplete one is “5% dextrose in water to keep the vein open” (TKO or KVO). This statement does not specify the rate of infusion and is not considered complete.

Vascular Access Devices

An infusion catheter, also known as a **vascular access device (VAD)**, is a plastic tube placed in a blood vessel to deliver fluids and medications. The specific type and purpose of the

therapy determine whether the infusion can be given safely through peripheral veins or if the large central veins of the chest are needed. Advances in catheter materials and insertion techniques have radically expanded the types of VADs currently used. This discussion includes the description of each type of catheter used for peripheral and central IV therapy. Seven major types are described:

- Short peripheral catheters
- Midline catheters
- Peripherally inserted central catheters (PICC)
- Nontunneled percutaneous central venous catheters (CVCs)
- Tunneled catheters
- Implanted ports
- Hemodialysis catheters

Assess the patient's needs for vascular access, and choose the device that has the best chance of infusing the prescribed therapy for the required length of time. Depending on the patient and type of VAD to be inserted, a topical anesthetic agent or intradermal lidocaine HCl 1% may be helpful to decrease patient discomfort. Obtain a health care provider's order and check for patient allergies before administering any anesthetic.

NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

A client receiving vancomycin intravenously reports that the peripheral IV insertion site has become painful and reddened. What is the nurse's first action?

- Report the change to the health care provider.
- Document the findings in the electronic patient record.
- Change the IV insertion site to a new location.
- Stop the infusion of the drug.

PERIPHERAL INTRAVENOUS THERAPY

Short infusion catheters are the most commonly used vascular access devices (VADs) for **peripheral IV therapy**. They are usually placed in the veins of the arm. Another catheter used for peripheral IV therapy is a midline catheter.

Short Peripheral Catheters

Short peripheral catheters are composed of a plastic cannula built around a sharp stylet extending slightly beyond the cannula (Fig. 15-2). The stylet (sharp) allows for the venipuncture, and the cannula is advanced into the vein. Once the cannula is advanced into the vein, the stylet is withdrawn. These catheters are designed with a safety mechanism to cover the sharp end of the stylet after it is removed from the patient. These stylets are hollow-bore, blood-filled needles

FIG. 15-2 BD Insite Autoguard IV catheter. With the push of a button, the needle instantly retracts, reducing the risk for accidental needle stick injuries.

that carry a high risk for exposure to bloodborne pathogens if needle stick injury occurs. A federal law enacted in 2000 amended the Bloodborne Pathogen Standards from the Occupational Safety and Health Administration (OSHA) requiring the use of catheters with an engineered safety mechanism to prevent needle sticks.

Insertion and Placement Methods

Short peripheral catheters are usually inserted into superficial veins of the dorsal surface of the hand and the forearm using sterile technique. In emergent situations, these catheters can be used also in the external jugular vein of the neck. *Avoid the use of veins in the lower extremities of adults, if possible, because of an increased risk for deep vein thrombosis and infiltration.*

Short catheters range in length from $\frac{3}{4}$ inch to $1\frac{1}{4}$ inch with gauge sizes from 26 gauge (the smallest) to 14 gauge (large bore). *Choose the smallest gauge catheter capable of delivering the prescribed therapy.* Current design allows for a thin-wall construction, providing a larger lumen (opening) without increasing the outer diameter. This design improves the fluid flow through the catheter while using a smaller gauge and thereby decreases the possibility of vein irritation from a large catheter. For example, a thin-walled 24-gauge Insite (BD Medical) catheter has about the same flow-rate ability as a 22-gauge non-thin-walled Angiocath (BD Medical). Larger gauge sizes allow for faster flow rates but also cause phlebitis more often. Table 15-1 lists each gauge size and its common uses.

Short peripheral catheters are allowed to dwell (stay in) for 72 to 96 hours but then require removal and insertion at another venous site. If the patient's therapy is expected to be longer than 6 days, a midline catheter or PICC should be chosen (O'Grady et al., 2011). When selecting the site for insertion of a peripheral catheter, consider the patient's

TABLE 15-1 CHOOSING THE GAUGE SIZE FOR PERIPHERAL CATHETERS

CATHETER GAUGE	INDICATIONS	APPROXIMATE FLOW RATES
24-26 gauge Smallest, shortest ($\frac{3}{4}$ -inch length)	Not ideal for viscous infusions Expect blood transfusion to take longer Preferred for infants and small children	24 mL/min (1440 mL/hr)
22 gauge	Adequate for most therapies, blood can infuse without damage	38 mL/min (2280 mL/hr)
20 gauge (1- $\frac{1}{4}$ -inch length)	Adequate for all therapies Most anesthesiologists prefer not to use a smaller size than this for surgery cases	65 mL/min (3900 mL/hr)
18 gauge	Preferred size for surgery Vein needs to be large enough to accommodate the catheter	110 mL/min (6600 mL/hr)
14-16 gauge	For trauma and surgical patients requiring rapid fluid resuscitation Needs to be in a vein that can accommodate it	

CHART 15-1 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Placement of Short Peripheral Venous Catheters

- Verify that the prescription for infusion therapy is complete and appropriate for infusion through a short peripheral catheter.
- For adults, choose a site for placement in the upper extremity. DO NOT USE THE WRIST.
- Choose the patient's nondominant arm when possible.
- Choose a distal site, and make all subsequent venipunctures proximal to previous sites.
- Do not use the arm on the side of a mastectomy, lymph node dissection, arteriovenous shunt or fistula, or paralysis.
- Avoid choosing a site in an area of joint flexion.
- Avoid choosing a site in a vein that feels hard or cordlike.
- Avoid choosing a site close to areas of cellulitis, dermatitis, or complications from previous catheter sites.
- Choose a vein of appropriate length and width to fit the size of the catheter required for infusion.

FIG. 15-3 The AccuVein AV300 is a vein illumination device that helps health care professionals locate veins for blood draw, IV infusion, and blood donation by projecting a pattern of light on the patient's skin to reveal the position of underlying veins on the skin's surface. The device uses red and infrared light, which the hemoglobin in blood absorbs to detect the position of the vein.

age, history, and diagnosis; the type and duration of the prescribed therapy; and, whenever possible, the patient's preference. [Chart 15-1](#) lists the major criteria for the placement of peripheral VADs.

Though not yet widely used in most clinical settings, vein transilluminators and ultrasound devices are now available as tools to assist in IV line placement. Several different types of portable vein transilluminators are available, such as VeinViewer, Veinlite LED, and AccuVein ([Fig. 15-3](#)). Although they may have different mechanisms of action, some using infrared light and some using laser, these devices penetrate only up to approximately 10 mm and so are limited to finding superficial veins.

Ultrasound-guided peripheral IV insertion can allow insertion into deeper veins. Although this technology is very valuable, it may increase the risks for complications. Arteries and nerves lie parallel to deep veins, and special training is needed to learn to identify these structures and avoid damaging them. In addition, when deeper veins are accessed, infiltration may go undetected until a significant amount of fluid has collected in the tissues. This complication can be particularly devastating if the solution is an irritant or vesicant. If these devices are not used, nurses must rely on sight and touch to insert an IV catheter.

For patients who need IV access but are at risk for fluid overload or do not need extra IV fluids, the peripheral vascular access device (VAD) can be converted into an intermittent IV lock, also called a *saline lock*. This device allows administration of specific drugs given IV push (e.g., furosemide [Lasix, Furoside 

Site Selection and Skin Preparation

The most appropriate veins for peripheral catheter placement include the dorsal venous network, basilic, cephalic, and median veins, as well as their branches ([Fig. 15-4](#)). However, cannulation of veins on the hand is not appropriate for older patients with a loss of skin turgor and poor vein condition and for active patients receiving infusion therapy in an ambulatory clinic or home care. Use of veins on the dorsal surface of the hands should be reserved for short-term infusion of non-vesicant and non-irritant solutions.

Mastectomy, axillary lymph node dissection, lymphedema, paralysis of the upper extremity, and the presence of dialysis grafts or fistulas alter the normal pattern of blood flow through the arm. Using veins in the extremity affected by these conditions requires a physician's request. Short peripheral catheters are not recommended for obtaining routine blood samples.

! NURSING SAFETY PRIORITY

Critical Rescue

Avoid veins on the palmar side of the wrist because the median nerve is located close to veins in this area, making the venipuncture more painful and difficult to stabilize. The cephalic vein begins above the thumb and extends up the entire length of the arm. This vein is usually large and prominent, appearing as a prime site for catheter insertion. However, the sensory branch of the median nerve can intersect with the cephalic vein up to three times from its origin to about 4 to 5 inches up the lateral aspect of the arm. Damage to the nerve can result in permanent loss of function or complex regional pain syndrome, type 2 (CRPS) ([Masoorli, 2007](#)). Reports of tingling, feeling "pins and needles" in the extremity, or numbness during the venipuncture procedure can indicate nerve puncture. If any of these symptoms occur, stop the IV insertion procedure immediately, remove the catheter, and choose a new site.

Winged needles ("butterfly needles") are easy to insert but are associated with a high frequency of infiltration. They are most commonly used for injection of single-dose drugs or for drawing blood samples. Like a short peripheral catheter,

A

B

FIG. 15-4 Common IV sites. **A**, Inner arm. **B**, Dorsal surface of hand.

winged needles should also have an engineered safety mechanism to house the needle when removed.

Aseptic skin preparation and technique before IV insertion are crucial. Catheter-related bloodstream infections (CR-BSI) can occur from a peripheral IV site. The CDC recommendations include:

FIG. 15-5 Midline catheter; the tip of this catheter resides in a peripheral vein.

- Perform hand hygiene before palpating the insertion site.
- Clip hair—do not shave.
- Ensure that skin is clean.
- Wear clean gloves for peripheral IV insertion; do not touch the access site after application of antiseptics.
- Prepare clean skin with 70% alcohol (or chlorhexidine) before peripheral venous catheter insertion.
- Apply povidone-iodine to the skin, and allow it to dry for at least 2 minutes.

Midline Catheters

Midline catheters can be anywhere from 3 to 8 inches long, 3 to 5 Fr, and double or single lumen. They are inserted through the veins of the upper arm. The median antecubital vein is used most often if insertion is done without the aid of ultrasound guidance. With ultrasound guidance, deeper veins can be accessed and the insertion site can be further above the antecubital fossa. The basilic vein is preferred over the cephalic vein because of its larger diameter and straighter path. It also allows greater hemodilution of the fluids and medications being infused. The catheter tip is located in the upper arm with the tip residing no further into the venous network than the axillary vein (Fig. 15-5). These catheters are used for therapies lasting from 1 to 4 weeks; however, there are no recommendations for the optimal dwell time. Because

of the extended dwell time, strict sterile technique is used for insertion and dressing changes for a midline catheter (Rosenthal, 2008). Additional education and skill assessment are required for the nurse to be qualified to insert midline catheters.

A midline catheter can be used when skin integrity or limited peripheral veins make it difficult to maintain a short peripheral catheter. Patients who have received anticoagulation and/or steroid therapy can also benefit from avoidance of repeated IV sticks and the subsequent excessive bruising and hematoma formation.

Other indications include:

- Fluids for hydration
- Longer than 6 days and up to 4 weeks of therapy such as:
 - Antibiotics
 - Heparin infusions for deep vein thrombosis
 - Bronchodilators, such as aminophylline
 - Steroids

Midline catheters are considered to dwell in the peripheral circulation; the recommendations for infusates are the same as for short peripheral IVs. Fluids and medications infused through a midline catheter should have a pH between 5 and 9 and a final osmolarity of less than 600 mOsm/L (Perucca, 2010; Rosenthal, 2008). The pH and osmolarity outside these parameters increase the risk for complications like phlebitis and thrombosis. Midline catheters should not be used for infusion of **vesicant medications**—drugs that cause severe tissue damage if they escape into the subcutaneous tissue (**extravasation**). At a midline tip location, larger amounts of the drug can extravasate before the problem is detected.

All parenteral nutrition formulas, including those with low concentrations of dextrose, and solutions that have an osmolarity greater than 600 mOsm/L should not be infused through a midline catheter. Do not draw blood from these catheters routinely. Midline catheters should not be placed in extremities affected by mastectomy with lymphedema, paralysis, or dialysis grafts and fistulas. When using a double-lumen midline catheter, do not administer incompatible drugs simultaneously administered through both lumens because the blood flow rate in the axillary vein is not high enough to ensure adequate hemodilution and prevention of drug interaction in the vein.

Some midline catheters are designed with pressure-sensitive valves located near the internal catheter tip (e.g., Groshong, made by Bard Access Systems) or in the external catheter hub (e.g., PASV, made by Boston Scientific). These valves open when pressure is applied, allowing for infusion and aspiration. However, when no pressure is applied, they are closed to prevent blood refluxing (backing) into the lumen or air entering the bloodstream. The manufacturers of both catheters state to use only a saline flush for lines with pressure-sensitive valves.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

The health care provider prescribes 3 L 5%D/0.45%NS to be infused over 24 hours. The nurse sets the rate at _____mL/hr of IV solution.

CENTRAL INTRAVENOUS THERAPY

In **central IV therapy**, the vascular access device (VAD) is placed in the central circulation, specifically within the superior vena cava (SVC) near its junction with the right atrium. Blood flow in the SVC is approximately 2 L/min compared with about 200 mL/min in the axillary vein. All central vascular access devices require confirmation of tip location by chest radiograph before solutions are infused (Hadaway, 2010a). However, the use of newer ultrasound systems, such as the Sherlock PICC tip location system, can decrease the need for repeated x-rays by confirming approximate catheter position. The practitioner inserts a specially designed magnetic stylet through the catheter before insertion into the patient so that the system can detect its tip location. These devices have been endorsed by the CDC and Agency for Healthcare Research and Quality (Moreau, 2008a).

A number of types of central vascular access devices (CVADs) are available, depending on the purpose, duration, and insertion site availability. Several recent improvements in catheter materials allow antimicrobial and heparin coatings to reduce infection risk and improve the longevity of the catheter. Newer central catheters also allow for rapid injection rates required for contrast studies.

Peripherally Inserted Central Catheters

A **peripherally inserted central catheter (PICC)** is a long catheter inserted through a vein of the antecubital fossa (inner aspect of the bend of the arm) or the middle of the upper arm. Nurses who insert these CVADs require special training and certification.

In adults, the PICC length ranges from 18 to 29 inches (45–72 cm) with the tip residing in the superior vena cava (SVC) (Fig. 15–6). Placement of the catheter tip in veins distal to the SVC is avoided. This inappropriate tip location, often called a *mid-clavicular catheter*, is associated with much higher rates of thrombosis than when the tip is located in the SVC. Mid-clavicular tip locations are used only when anatomic or pathophysiologic changes prohibit placing the catheter into the SVC.

PICCs should be inserted early in the course of therapy before veins of the extremity have been damaged from multiple venipunctures and infusions. Insertion methods using guidewires and ultrasound systems greatly improve insertion success. The basilic vein is the preferred site for insertion; the cephalic vein can be used if necessary. *Sterile technique is used for insertion to reduce the risk for catheter-related bloodstream infections (CR-BSIs). Before the catheter can be used for infusion, a chest x-ray indicating that the tip resides in the lower SVC is required when the catheter is not placed under fluoroscopy.*

PICCs are available in single-, dual-, or triple-lumen configurations and are available with both the Groshong valve and the pressure-activated safety valve (PASV). PICCs are also available as “Power PICCs” and can be used for contrast injection at a maximum of 5 mL/sec and a maximum pressure of 300 psi. They can also be connected to transducers and used to monitor central venous pressure (Bard Access Systems, 2011).

The most common complications from PICCs include phlebitis, thrombophlebitis, and CR-BSIs. Thrombophlebitis can be very serious and threatens the integrity of the vein.

FIG. 15-6 Peripherally inserted central catheter (PICC) is placed peripherally in a vein of the upper arm with the tip resting in the superior vena cava.

CR-BSI has been noted to be less frequent in PICCs than in other central venous catheters (CVCs) because of the insertion site in the upper extremity. The cooler, drier skin of the upper arm has fewer types and numbers of microorganisms, leading to lower rates of infection. Accidental arterial puncture or excessive bleeding can occur on insertion and is controlled by direct pressure. Infiltration and extravasation are rare. Insertion complications such as pneumothorax associated with other CVCs do not occur with PICCs.

PICCs can accommodate infusion of all types of therapy because the tip resides in the SVC where the rapid blood flow quickly dilutes the fluids being infused. Therefore there are no limitations on the pH or osmolality of fluids that can be infused through a PICC. For example, patients requiring lengthy courses of antibiotics, chemotherapy agents, parenteral nutrition formulas, and vasopressor agents can benefit from this type of catheter. PICCs have been reported to dwell successfully for months or even years; however, the optimal dwell time is not known.

PICCs can be used for blood sampling; however, lumen sizes of 4 Fr or larger are recommended. Using lumens with small diameters may not yield a sample capable of producing the needed test results. Transfusion of blood through a PICC

usually requires the use of an infusion pump. Packed red blood cells are cold and viscous. The length of the catheter adds resistance and may prevent the blood from infusing within the 4-hour limit.

Teach patients with a PICC to perform usual ADLs; however, they should avoid excessive physical activity. Muscle contractions in the arm from physical activity like heavy lifting can lead to catheter dislodgment and possible lumen occlusion. PICCs may be contraindicated in paraplegic patients who rely on their arms for mobility.

PICC insertion is commonly performed in the patient's hospital room, an outpatient treatment facility, or the imaging department. Regardless of where they are inserted, the same precautions must be taken as with any other central line insertion using the catheter-related bloodstream infection (CR-BSI) prevention bundle. Major components of this prevention bundle include:

- Hand hygiene
- Maximal barrier precautions upon insertion
- Chlorhexidine skin antisepsis
- Optimal catheter site selection and post-placement care with avoidance of the femoral vein for central venous access in adult patients
- Daily review of line necessity with prompt removal of unnecessary lines

! NURSING SAFETY PRIORITY

Action Alert

The INS recommendation for flushing PICC lines not actively used is 5 mL of heparin (10 units/mL) in a 10-mL syringe at least daily. Ten mL of sterile saline is used to flush before and after medication administration, and 20 mL of sterile saline is flushed after drawing blood. Always use 10-mL barrel syringes to flush any central line because the pressure exerted by a smaller barrel poses a risk for rupturing the catheter.

Nontunneled Percutaneous Central Venous Catheters

Nontunneled percutaneous central venous catheters (CVCs) are inserted by a physician through the subclavian vein in the upper chest or the internal jugular veins in the neck using sterile technique. Occasionally the patient's condition may require insertion of the CVC in a femoral vein, but the rate of infection is very high. If the femoral site must be used, it is removed as soon as possible.

CVCs are usually 7 to 10 inches (18 to 25 cm) long and have one to as many as five lumens ([Fig. 15-7](#)). These catheters are also available with antimicrobial coatings such as chlorhexidine and silver sulfadiazine. The tip resides in the superior vena cava (SVC) and is confirmed by a chest x-ray. Nontunneled percutaneous CVCs are most commonly used for emergent or trauma situations, critical care, and surgery. There is no recommendation for optimal dwell time. However, these catheters are commonly used for short-term situations and are *not* the catheter of choice for home care or ambulatory clinic settings.

Insertion of these central catheters requires the patient to be placed in the Trendelenburg position, usually with a rolled towel between the shoulder blades. This position may be difficult or contraindicated for patients with respiratory conditions, spinal curvatures, and increased intracranial pressure,

FIG. 15-7 The Edwards Lifesciences PreSep central venous catheter (CVC); often placed in the subclavian or internal jugular vein with the tip of the catheter resting in the superior vena cava.

especially for older adults. Trauma, surgery, or radiation in the neck or chest prohibits the use of these devices as well. The presence of a tracheotomy increases the risk for cross-contamination of the insertion site. The warmer, moister skin of the neck and upper chest has more types and higher numbers of microorganisms, resulting in more CR-BSIs with this type of catheter.

Tunneled Central Venous Catheters

Tunneled central venous catheters are VADs that have a portion of the catheter lying in a subcutaneous tunnel, separating the points where the catheter enters the vein from where it exits the skin. This separation is intended to prevent the organisms on the skin from reaching the bloodstream (Fig. 15-8). The catheter has a cuff made of a rough material that is positioned inside the subcutaneous tunnel. These cuffs commonly contain antibiotics, which also reduce the risk for infection. The tissue granulates into the cuff, providing a mechanical barrier to microorganisms and anchoring the catheter in place.

The design of tunneled CVCs requires surgical techniques for insertion and removal. Single-, dual-, and triple-lumens are available. These catheters were originally named for the physicians who designed them, including Broviac, Hickman, and Leonard catheters.

Tunneled catheters are used primarily when the need for infusion therapy is frequent and long-term. Patients needing

FIG. 15-8 Tunneled catheter. A portion of this catheter lies in a subcutaneous tunnel, separating the point where the catheter enters the vein from where it exits the skin.

parenteral nutrition for months, years, or the remainder of their life commonly choose a tunneled catheter. Tunneled catheters are also chosen when several weeks or months of infusion therapy are needed and a PICC is not a good choice. For example, paraplegic patients needing 6 to 8 weeks of antibiotics are not good candidates for a PICC because of the excessive use of the upper extremities for mobility. Some oncology patients may prefer a tunneled catheter instead of an implanted port because they cannot tolerate the needle sticks required for accessing those devices.

Implanted Ports

Implanted ports are very different from other central vascular access devices (CVADs). They consist of a portal body, a dense septum over a reservoir, and a catheter. They can be single- or double-lumen and come in various sizes. A subcutaneous pocket is surgically created to house the port body. The catheter is inserted into the vein and attached to the portal body. The septum is made of self-sealing silicone and is located in the center of the port body over the reservoir; the catheter extends from the side of the port body. The incision is closed, and no part of the catheter is visible externally; therefore this device has the least impact on body image (Fig. 15-9).

Some implanted ports are power-injectable and can be used for obtaining contrast-enhanced computed tomography (CECT). These devices can withstand 5 mL/sec at up to 300 psi pressure. The BARD PowerPort can be identified by palpation of three bumps on the top of the septum and a triangular-shaped port. Be careful not to press firmly on the bumps because it can be painful to the patient. Be sure to use a power-injection-rated noncoring needle with this type of port when it is used for this purpose. These needles come

FIG. 15-9 Positioning of an implanted port.

with labeling identifying that they are power-injection rated (Fig. 15-10).

Venous ports may be placed on the upper chest or the upper extremity. The venous catheter may enter either the subclavian or internal jugular vein. Although an implanted port is most commonly used in the venous system, the catheter may be placed in arteries, the epidural space, or the peritoneal cavity, with the port pocket located over a bony prominence.

Implanted ports are accessed by using a noncoring needle (a common brand name is *Huber*) that is specially designed with a deflected tip (Fig. 15-11). This design slices through the dense septum without coring out a small piece of it, thus preserving the integrity of the septum. Port bodies placed in the chest have a larger septum and usually tolerate about 2000 punctures. Port bodies placed in the upper extremity are smaller and are rated to tolerate about 750 punctures.

Before puncture, palpate the port to locate the septum. Carefully palpate to feel the shape and depth of the port body to ensure puncture of the septum, not the attached catheter. Some have attached extension sets and wings to stabilize the needle. One important feature is an engineered safety mechanism to contain the needle when it is removed from the septum. Because the dense septum holds tightly to the needle, there can be a rebound when it is pulled from the septum, often resulting in needle stick injury to the nurse.

Implanted ports need to be flushed after each use and at least once a month between courses of therapy. This procedure is done to prevent clot formation in the internal chamber of the port and is often referred to as “locking” or “de-accessing.” The INS recommendation for locking or de-accessing a port is 5 mL of 100 units heparin/mL. However, locking a central line to prevent it from clotting is controversial and under-researched (Gorski et al., 2010). When the port is not accessed, there is no external catheter requiring a dressing. Puncture of the skin over the port is required to gain

FIG. 15-10 A noncoring needle for accessing an implanted power port.

FIG. 15-11 Noncoring needle. The safety mechanism traps the needle to prevent needle stick injury.

! NURSING SAFETY PRIORITY

Drug Alert

Before giving a drug through an implanted port, always check for blood return. If there is no blood return, hold the drug until patency and adequate noncoring needle placement of the port are established. Serious extravasations of vesicant drugs can occur because a fibrin sheath (flap or tail) may occur at the tip of the catheter, clot it, and cause retrograde subcutaneous leakage.

access to the port body, causing pain for some patients. Topical anesthetic creams can be used to make the access procedure more tolerable.

Hemodialysis Catheters

Hemodialysis catheters have very large lumens to accommodate the hemodialysis procedure or a pheresis procedure that harvests specific blood cells. They may be tunneled for long-term needs or nontunneled for short-term needs. A hemodialysis catheter is critical to the management of renal failure and must function well. Catheter-related bloodstream infections (CR-BSIs) and vein thrombosis are common problems; therefore this catheter should not be used for administration of other fluids or drugs except in an emergency.

The concentration of heparin used to lock hemodialysis catheters ranges from 1000 to 10,000 units/mL. Researchers have demonstrated that using 1,000 units/mL reduces the incidence of post-insertion bleeding but may be associated with an increased need for recombinant tissue plasminogen activator (tPA) to maintain patency. A flush of 1000 units heparin/mL or a solution of 4% sodium citrate in the amount of the dwell volume of each lumen has been recommended (Moran & Ash, 2010). Heparin is most often used because sodium citrate has not been as commercially available in the preparation needed. To prevent systemic anticoagulation and subsequent bleeding, be sure to aspirate the heparin from the lumens before use.

INFUSION SYSTEMS

Nurses administering infusion therapies need to understand how infusion systems work. This knowledge ensures that the patient can benefit from a particular system's advantages while minimizing any potential complications.

Containers

Infusion containers are made of glass or plastic. *Glass* bottles were the original fluid container to be mass produced. They are easily sterilized, and it is easy to read the amount of fluid remaining in the bottle. Also, glass is inert and so cannot interact with some drugs like plastic can. However, glass bottles are heavy and cannot easily be used in many situations, such as patient transport during emergencies. These containers require an air vent for fluids to flow freely from them. The most common method is to use an administration set with a special filtered vent. Some bottles may have a straw tube open to the room air through the rubber stopper in the bottle and extending to above the level of the fluid. Bottles with a venting straw do not have a barrier to prevent contaminants in the air from entering the fluid.

Plastic containers are considered *closed systems* because they do not rely on outside air to allow the fluid to infuse. Instead, atmospheric pressure pushes against the flexible sides of the container, allowing the fluid to flow by gravity. For this reason, plastic containers do not require vented administration sets. These containers are lightweight, resistant to breaking, easier to store, and easy to use in emergency conditions. Therefore they are used more frequently than glass containers.

All plastic containers were commonly made of polyvinyl chloride (PVC). To increase flexibility and strength, PVC required the addition of a plasticizer, such as

di-2-ethylhexyl-phthalate or DEHP. Concern has been growing in the past few years over the exposure of patients to this chemical because it can leach from the plastic fluid container or tubing and infuse into the patient with the IV fluid or medication. The Food and Drug Administration (FDA) has determined that there is little to no risk posed to most patients by exposure to the amount of DEHP released from IV bags with infusion of crystalloids or drugs. However, there is concern about the buildup of chemical exposure from many sources over a lifetime and specifically the potential effects of DEHP on the development of the male reproductive system. Therefore many hospitals are using PVC-free or DEHP-free IV bags, especially for high-risk groups such as neonates and children (Food and Drug Administration [FDA], 2009).

One disadvantage of removing DEHP from the plastic bags is that the bags are less pliable and more prone to rupture. Some institutions do not allow these bags to be sent through a pneumatic tube system because the pressure exerted has caused the bags to rupture during transport.

A problem with plastic containers is that they are not compatible with insulin, nitroglycerin, lorazepam (Ativan), fat emulsions, and lipid-based drugs. Nitroglycerin and insulin adhere to the walls of the PVC container, making it impossible to know exactly how much medication the patient is receiving. There is evidence that a priming volume of 20 mL of insulin solution is required to minimize the effect of insulin absorption losses to the plastics in IV lines (Goldberg et al., 2006).

Another concern with plastic bags is the accuracy of reading the amount of fluid remaining in the container. The middle graduations have been shown to be 10% above or below the actual amount of fluid, but the first and last markings could be inaccurate by as much as 40% (Perucca, 2010).

Semi-rigid containers are made of plastic but offer some of the benefits of glass, such as the absence of plasticizers and drug incompatibility. These containers are lightweight and unbreakable but are more bulky and less flexible. They also require an air vent to allow the fluid to flow freely.

! NURSING SAFETY PRIORITY

Action Alert

Regardless of the type of fluid container being used, check it for cracks or pinholes before use. Always observe the fluid for **turbidity** (cloudiness) or any unusual color that could indicate contamination.

Administration Sets

The administration set is the connection between the catheter and the fluid container. Numerous sets are available in many different configurations. The type and purpose of the infusion determine the type of administration set needed. Some sets are *generic*, meaning that they are appropriate for most infusions. Other sets are used for specific types of infusions, such as blood transfusion. Still others are *dedicated*, meaning that they must be used with a specific manufacturer's infusion controlling device. Information that describes their proper use is provided on the packaging of administration sets.

Secondary Administration Sets

A primary continuous administration set is used to infuse the primary IV fluid by either a gravity infusion or an electronic

infusion pump. A short **secondary administration set**, also known as a **piggyback set**, is attached to the primary set at a Y-injection site and is used to deliver intermittent medications. Directions and diagrams for use are typically on the packaging. Once attached, these sets should remain connected together as an infusion system. If multiple intermittent medications are required, it may be possible to use only one secondary set rather than a secondary set for each medication. This depends on the compatibility of the drugs. Back flushing from the primary IV fluid may be performed to maintain the closed system and allow the secondary set to be used for multiple doses of the same or compatible medications. Change these sets every 72 to 96 hours.

Intermittent Administration Sets

When no primary continuous fluid is being infused, an intermittent administration set is used to infuse multiple doses of medications through a catheter that has been capped with a needleless connection device. The medication bag from the previous dose is removed and the new one attached. The sterile cap covering the distal end of the set is removed, and the set is attached to the catheter. Because both ends of the set are being manipulated with each dose, the INS standards of practice state that this set should be changed every 24 hours. If a secondary administration set is detached from the primary set, it should be considered an intermittent set and changed every 24 hours (INS, 2006). When the administration set is used for infusion of lipid solutions, change it every 24 hours. Change blood tubing within 4 hours and tubing used to infuse propofol (Diprivan) every 6 to 12 hours (McGoldrick, 2010). These fluids are thick and can clog the tubing.

Administration sets are sterile in the fluid pathway and under the sterile caps on each end of the set. The set is not packaged as a completely sterile product and cannot be added to a sterile field. Careful attention is required to maintain the sterility of the spike and the connection end of the tubing to prevent introduction of microorganisms into the catheter and bloodstream.

Add-on Devices

Several other types of add-on devices include short extension sets, injection caps, and filters. Extension sets may be packaged as a sterile product for adding to a sterile field; however, always check the product label to ascertain this information.

Administration sets have two ways to connect to the catheter hub: a slip lock or a Luer-Lok. The *slip lock* is a male end that slips into the female catheter hub. A *Luer-Lok* connection has the same male end with a threaded collar that requires twisting onto the corresponding threads of the catheter hub. All connections, including *extension sets*, should have a Luer-Lok design to ensure that the set remains firmly connected. Loose connections lead to fluid leakage and increase the risk for contamination and subsequent bloodstream infection. When using a central venous catheter, a Luer-Lok connection is critical to reduce the risk for air embolism. Tape is not considered an adequate mechanism for securing set connections.

Luer-Lok devices may be purposefully or accidentally disconnected. Patients or visitors may disconnect the system to allow the patient to get out of bed or the chair. Or, the device may become accidentally disconnected when the patient

turns or moves. In either case, be sure to reconnect the device by following the proper sequence to reassemble the IV system components. Fatalities have resulted when nurses have reconnected IV tubing to a tracheostomy or blood pressure cuff.

Filters may be part of the administration set or may be separate add-on pieces. Their purpose is to remove particulate matter, microorganisms, and air from the infusion system. Filter sizes depend on the pore size, with common sizes being 5 microns intended to remove gross particles, 1.2 microns used to filter lipid-containing parenteral nutrition, and 0.22 microns intended to remove all particles and microorganisms. Filters should be placed as close to the catheter hub as possible.

Particulate matter in the IV fluid, a primary reason to use filters, comprises undissolved, unintended substances and may include rubber pieces, glass particles, cotton fibers, drug particles, paper, and metal fibers. These particles become trapped in the small circulation of the lungs. A red blood cell is about 5 microns in diameter and is the largest size that can pass through the pulmonary capillary bed, and yet IV fluids may contain particles larger than this. For patients receiving infusion therapy for long periods, a significant number of particles could block the blood flow through the pulmonary circulation. Microcirculation in the spleen, kidneys, and liver could also be affected. Particulate matter has also been implicated in the development of phlebitis in peripheral veins.

Other concerns with using filters include the possibility for their rupture, their use with certain drugs that bind to the filter surface, using the correct size of filter for drugs with large molecules, and choosing a filter that will tolerate the pressure exerted by infusion pumps. Rupture is most commonly associated with the exertion of high pressure exceeding the limit tolerated by the specific filter. Some drugs cannot be filtered because they are retained inside the filter because of their chemical nature or molecule size. For these reasons, medication filtration during the process of admixing is commonly used today as an alternative to final filtration at the bedside. Drugs of a very small quantity should be administered below the filter.

Filters used on blood administration sets have much larger pore size and are not interchangeable with filters used for fluids and medications. A standard blood filter ranges from 170 to 220 microns and removes microclots and other debris caused by blood collection and storage. Microaggregate filters have a pore size of 20, 40, or 80 microns and are used to remove degenerating platelets, white blood cells, and fibrin strands. Leukocyte-removal filters are used to remove white blood cells that cause febrile and allergic blood transfusion reactions, cytomegalovirus, and some herpes viruses.

Needleless Connection Devices

In July 1992, the Occupational Safety and Health Administration (OSHA) published guidelines entitled *Occupational Exposure to Bloodborne Pathogens, Final Rule*. This document requires health care organizations to initiate engineering controls “that isolate or remove the bloodborne pathogen hazard from the workplace.” This standard was amended in 2001 with the passage of the Needlestick Safety and Prevention Act. This regulation requires the use of devices engineered with safety mechanisms and mandates that staff who perform these tasks be directly involved with selecting products. It also requires each employer to maintain a sharps injury log with

FIG. 15-12 Example of a needleless connector.

details of each incident. Many products are designed to minimize health care workers' exposure to contaminated needles. Luer-activated devices are the most common design for needleless systems today.

Although these devices have reduced the incidence of accidental needle sticks for health care professionals, concern remains about a possible increase in the risk for catheter-related bloodstream infections (CR-BSIs) (Rosenthal, 2006a). This concern stems from the crevices created with the diaphragm and Luer-Lok design. Blood and bacteria can be trapped in the crevices, and meticulous cleaning is required with each use.

Various designs are available for connectors that provide positive or negative displacement of fluid when the needleless syringe is removed. Needleless positive-pressure valve (PPV) connectors were developed to prevent backflow of blood into the IV catheter, thereby decreasing chances of thrombus formation and CR-BSI. Several newer connectors are silver-impregnated to reduce bacterial growth (Fig. 15-12). Be sure to check which type of connector valve is used in your facility because the flushing technique differs depending on type. Researchers have found conflicting results about the relationships between these devices and CR-BSI and catheter occlusion (Khalidi et al., 2009; Mitchell et al., 2009; O'Grady et al., 2011).

Conclusive studies are needed to determine the best design for needleless systems. Until then, implement these interventions to reduce infection risk:

- Clean all needleless system connections vigorously with antimicrobial for 30 seconds (usually 70% alcohol or 2% chlorhexidine swabs) before connecting infusion sets or syringes, paying special attention to the small ridges in the Luer-Lok device.
- Do not tape connections between tubing sets.
- Use evidence-based hand hygiene guidelines from the Centers for Disease Control and Prevention (CDC) and the Occupational and Safety Health Administration (OSHA) in the United States.

Rate-Controlling Infusion Devices

The ability to regulate the rate and volume of infusions is critical to the safe and accurate administration of

medications and fluids to patients. Nurses have a choice of numerous devices that can be electronically or mechanically regulated.

Electronic infusion devices (IV pumps) are used universally in acute care institutions. They are also used in long-term care settings and at home. In addition, "smart pumps" provide the latest infusion computer technology to promote patient safety and save nursing time. *Remember that the use of pumps does not decrease your responsibility to carefully monitor the patient's infusion site and the infusion rate.*

In inpatient settings, IV pumps are pole-mounted. As their name implies, these electronic devices with battery backup pump drugs or fluids under pressure. They accurately measure the volume of fluid being infused by using one of three mechanisms:

- A syringe-type mechanism that fills and empties
- A wavelike, peristaltic action that pushes fluid along the tubing
- A series of microchambers that fill and empty

Regardless of the pumping mechanism, these devices require dedicated cassette tubing designed to match the pump.

Syringe pumps use an electronic or battery-powered piston to push the plunger continuously at a selected milliliter-per-hour rate. The use of syringe pumps is limited to small-volume continuous or intermittent infusions and depends on the syringe size. Antibiotics and patient-controlled analgesia are frequently delivered with syringe pumps. Patients requiring fluid restrictions can also benefit from using a syringe pump because smaller yet accurate volumes can be used to dilute medications.

Ambulatory pumps are generally used for home care patients and allow them to return to their usual activities while receiving infusion therapy. These pumps have a wide range of sizes, with some requiring a backpack, but they usually weigh less than 6 pounds. They are typically used to accurately deliver continuous infusions, such as parenteral nutrition, pain medication, and many programmable drug schedules. Frequent battery recharging or replacement is usually necessary.

Electronic infusion devices can be programmed in many different ways and require a thorough knowledge of the specific brand being used. Infusion rate and the volume to be infused are usually entered in single milliliter increments, but some can be programmed as fractions of a milliliter. Some pumps allow the rate to be programmed to taper or ramp up and down at the beginning and ending of the infusion. Secondary syringe infusion, secondary infusion rate, remote site programming, adjustable infusion pressure, and integration into the nurse call system also are possible.

Electronic infusion devices have a variety of alarms, such as air-in-line, upstream and downstream occlusion, infusion complete, and low-battery or power warnings. All devices must have some mechanism to prevent free flow of the infusing fluid or medication. When the cassette or tubing is removed from the pump, this mechanism automatically stops fluid flow until it is properly replaced in the pump. This safety measure prevents accidental rapid infusion of large amounts of fluid or medication, which could lead to serious clinical problems.

In the past few years, **smart pumps** (infusion pumps with dosage calculation software) have been promoted to reduce adverse drug events (ADEs). Incorrect programming of

pumps without this feature is one of the most common types of drug errors, especially in hospitals. Multiple libraries of drug information are stored in the pump manufacturer's medical management system. This software allows the facility to pre-program dosing limits, especially for high-alert drugs. Examples of smart pumps are the B. Braun Outlook® 400ES and the Baxter Sigma Spectrum infusion system.

The newest development in smart pumps is a wireless network connection. Drug libraries can be updated via a wireless connection, thus eliminating the necessity of manually updating each pump. In addition to preventing drug errors, smart pump systems record potential errors that would have occurred without these safety mechanisms (Jacobs, 2006).

Dose-track technology is intended to transmit the infusion data to the institution's pharmacy so that the correct patient receives the correct medication. Dose-guard technology alerts the nurse if institution-defined dose limits are exceeded. These newer technologies provide safeguards for patients to keep them safe. However, the "smarter" the pump, the more extensive the programming steps are and the more alarms that the nurse must respond to. In addition, technology and wireless connections can fail. The challenge for nurses is to maintain the skill of manual dose calculation and rate control, to acknowledge and validate all alarms, and to guard against becoming desensitized to alarms.

Mechanically regulated devices can be used to deliver intermittent medications such as antibiotics or continuous pain medications in community-based health or home care setting. In acute care settings, devices called "infusers" may be found in surgical services. They are powered by positive pressure from the collapsing balloon or roller returning to its coiled position.

The systems include elastomeric balloons, spring-coiled syringes and containers, and a multi-chambered fluid container placed in a mechanical roller (Accufuser or On-Q PainBuster) (Fig. 15-13). These small portable devices do not require power sources such as batteries or electricity. They deliver a preset infusion rate, and fluid volume is determined by the size of the fluid container; however, most hold only 50 to 100 mL.

NURSING CARE FOR PATIENTS RECEIVING INTRAVENOUS THERAPY

Educating the Patient

The current trend in health care demands that we partner with our patients to provide the best patient-centered care. In 2010, The Joint Commission added the requirement that all patients who have central lines placed in the hospital must have education on prevention of catheter-related bloodstream infection (CR-BSI). Before catheter insertion, educate the patient and family about:

- The type of catheter to be used
- Hand hygiene and aseptic technique for care of the catheter
- The therapy required
- Alternatives to the catheter and therapy
- Activity limitations
- Any signs or symptoms of complications that should be reported to a health care professional

FIG. 15-13 On-Q PainBuster pump (mechanical infuser).

Provide written information before placement of a long-term catheter, and continue to assess the patient's knowledge level and provide more information or answers as needed. Most manufacturers of PICCs, tunneled catheters, and implanted ports provide patient information booklets. However, specific information about the chosen procedures and supplies may be required. Conversation and pictures will be helpful for patients who are literacy challenged (have a low reading level).

Performing the Nursing Assessment

All central VADs require a postinsertion chest x-ray to document the tip location. The initial verbal and subsequent written report should contain specific information about the catheter tip location in relation to anatomic structures. The nurse's knowledge of accurate tip location is required before beginning infusion through the catheter. Repeating the x-ray during catheter use may be necessary if the patient reports unusual pain or sensation.

Nursing assessment for all infusion systems should be systematic. Begin with the insertion site and work upward, following the tubing. Know the type of catheter your patient has in place. Be sure to find out the length of catheter, the insertion site, and tip location to perform a complete assessment. Assess the insertion site by looking for redness, swelling, hardness, or drainage. Lightly palpate the area over the dressing. When a midline catheter or PICC is used, assess the entire extremity and upper chest for signs of phlebitis and thrombosis. When a tunneled catheter is used, assess the exit site, the entire length of the tunnel, and the point where the catheter enters the vein. For a well-healed catheter, it may not be possible to detect the vein entrance site. On newly inserted catheters, there could be a small puncture site with a suture or securement device. For implanted ports,

FIG. 15-14 The StatLock provides a standardized method to prevent catheter movement.

assess the incision and surgically created subcutaneous pocket.

Assess the integrity of the dressing, making sure it is clean, dry, and adherent to the skin on all sides. Check all connections on the administration set, and ensure that they are secure. Be sure they are not taped. Check the rate of infusion for all fluids by either counting drops or checking the infusion pump. Assess the amount of fluid that has infused from the container. Is it accurate, or is it infusing too fast or too slow? Adjust the rate to the prescribed flow rate. Check all labels on fluid containers for the patient's name and fluid or medication. *Be sure that the correct solution is being infused!*

! NURSING SAFETY PRIORITY

Action Alert

Avoid taking blood pressures in an extremity with any type of catheter in place. If a short peripheral catheter is being used for continuous infusion, the compression while taking the blood pressure can increase venous pressure, causing fluid to overflow from the puncture site and infiltration. When a midline catheter or PICC is being used, compression from the blood pressure cuff could increase vein irritation and lead to phlebitis.

Draw blood samples in the extremity opposite from all catheters. Blood should not be drawn from a venipuncture site proximal to (above) an infusing peripheral catheter because the infusing fluid could alter the results of the test to be performed. Venipuncture at or near the insertion site of a midline catheter or PICC could damage the catheter and add to areas of venous inflammation.

Securing and Dressing the Catheter

Adequate catheter securement is vital to prevent many complications. Tape, sutures, and specially designed securement devices can be used for this purpose. For a short peripheral catheter, tape strips are most common; however, the tape should be *clean*. Tape strips from a peripheral IV start kit are preferred. Strips of tape should not be taken from rolls of tape moved between patient's rooms, from other procedures, or from uniform pockets. Precutting tape and placing it on the patient's bedrails, your uniform or scrubs, or other object should also be avoided to prevent infection.

Newer *securement devices* are designed for all catheter types and provide an evidence-based method to prevent VAD movement (INS, 2006). Recent studies have shown that these devices, such as the StatLock IV stabilization device, prevent peripheral and central catheters from becoming dislodged (Fig. 15-14). In addition, they prevent catheter complications, like phlebitis and infiltration. Use of securement devices, rather than tape, also provides significant cost savings by decreasing the number of IV restarts. To prevent skin tears, remove the adhesive on a StatLock with 70% alcohol.

PICCs and nontunneled percutaneous central catheters may be sutured in place; however, this creates additional breaks in the skin that could become infected. If these sutures are loose or broken, notify the health care provider to replace them. IV catheter sutures are being replaced with securement devices in some facilities.

Tunneled catheters usually have sutures placed near the skin exit site, which are removed after the tunnel has healed. The incision over a port pocket will have sutures until it has healed.

Sterile dressings used over the insertion site protect the skin and puncture site. For a short *peripheral* catheter, the transparent membrane dressings do not require routine changes; site rotation is every 72 to 96 hours. Tape and sterile gauze or a transparent membrane dressing can be used for midline catheters and all types of *central venous* dressings. Tape and gauze dressings should be changed every 48 hours; transparent membrane dressings, such as Tegaderm, are changed at least every 7 days (Gorski, 2007). The initial dressing on a midline catheter or PICC is usually tape and gauze, changed

! NURSING SAFETY PRIORITY

Action Alert

Site protection may be needed for short peripheral catheters or for port access needles. Plastic shields can be placed over the site to prevent accidental bumping or pressure from clothing. Make sure you can easily assess the site frequently. Never place a restraint or opaque dressing over a peripheral IV site, especially when infusing an irritant or vesicant.

within 24 hours after insertion because some bleeding is likely. Transparent membrane dressings can be used for subsequent dressing. Document all sterile dressing changes and IV site assessments in the appropriate patient record per agency policy.

When changing the dressing, remove it by pulling laterally from side to side. It can also be removed by holding the external catheter and pulling it off toward the insertion site. *Never pull it off by pulling away from the insertion site because this could dislodge the catheter!*

After removing the dressing from a midline catheter or any central venous catheter, note the external catheter length. Compare this length with the original length at insertion. If the length has changed, the catheter tip location has also changed and may no longer be in a vein appropriate for infusion. Follow agency policy or notify the health care provider about the length change. A repeat chest x-ray may be needed, and careful assessment of the type of therapy and remaining length of therapy will likely be required.

Protect the external catheter, dressing, and all attached tubing from water because it is a source of contamination. While bathing, be sure that the unlicensed assistive personnel (UAP) cover the extremity. Plastic trash bags can be taped over the extremity; however, devices specially designed for this purpose are more convenient for the patient to use.

DECISION-MAKING CHALLENGE

Evidence-Based Practice; Safety

You are a charge nurse on a busy medical unit where almost every patient has some type of IV therapy. While making rounds, you notice that an experienced nurse orientee pre-cut tape strips for securing a patient's peripheral VAD and placed them on the edge of the overbed table. After connecting the IV tubing to the catheter, he removed his gloves to apply the tape. You also notice that he did not label the tubing with today's date, time, and his initials as per agency policy. Today is his last day of orientation before having a full patient assignment on the unit.

1. What violations of the evidence-based interventions for preventing the IHI catheter-related bloodstream infection (CR-BSI) prevention bundle did you notice?
2. What will you do or say at this time while the orientee is caring for the patient?
3. After leaving the patient's room, what will you say to the orientee?
4. How can these violations be prevented in the future? What is the value of memory checklists to ensure consistency among nurses caring for patients with IVs?

Changing Administration Sets and Needleless Connectors

Primary and secondary administration sets are changed using sterile technique usually every 72 or 96 hours; however, certain types of fluids require more frequent change. These include lipid emulsion, blood products, and drugs such as propofol. Identify when the tubing was changed according to agency protocol, and document.

Plan the change of administration sets and fluid containers to occur at the same time, if possible, to minimize the number of times the system is opened. For short peripheral catheters, the administration set and catheter should also be changed at the same time to avoid excessive manipulation of the catheter. Document these changes per agency policy.

Needleless connector devices can be changed when the administration set is changed. If it is being used for intermittent infusions, the device should be changed at least once per week. Fluid leakage from the device indicates the integrity has been compromised, and it should be changed immediately.

Precautions to prevent *air emboli* are required when changing the set or connectors attached to any catheter; however, central venous catheters require special attention. Most catheters have a pinch clamp that can be closed during this procedure. Techniques used to increase the intrathoracic pressure and prevent air embolism during IV set change include:

- Placing the patient in a flat position to ensure that the catheter exit site is at or below the level of the heart
- Asking the patient to perform a Valsalva maneuver by holding his or her breath and bearing down
- Timing the IV set change to the expiratory cycle when the patient is spontaneously breathing
- Timing the IV set change to the inspiratory cycle when the patient is receiving positive-pressure mechanical ventilation.

Controlling Infusion Pressure

Fluid flow through the infusion system requires that the pressure on the external side be greater than the pressure at the catheter tip. Fluid flow can be slowed or obstructed by many causes. At or above the catheter hub, kinked tubing, tubing or syringe diameter, and fluid temperature or viscosity could create resistance to flow. Inside the catheter lumen, resistance is created by the catheter length and diameter or by deposits of fibrin, thrombus, or drug precipitate. Near the catheter tip, resistance to flow comes from the catheter tip impinging on the vein wall, thrombus, or venous spasm.

All catheter manufacturers have warnings about the use of excessive pressure. Gravity and infusion pumps do not exert pressure too high for the catheter to handle; however, excessive pressure from syringes can lead to catheter damage. For this reason, use 10-mL syringes for central venous catheters. Although these larger syringes generate less pressure, it is still possible to reach excessive pressure levels if great force is applied against a syringe attached to a catheter that is partially occluded.

Flushing the Catheter

Catheter flushing prevents contact between incompatible drugs and maintains patency of the lumens. Normal saline alone or normal saline followed by heparinized saline may be used. When using valved catheters and certain positive fluid-displacement needleless devices, normal saline alone is

NURSING SAFETY PRIORITY

Critical Rescue

Assess catheter patency carefully before each use. Use sterile technique to flush with normal saline while applying slow, gentle pressure to the syringe plunger. If you feel any resistance, stop the procedure immediately! If you continue, catheter rupture or forcing a blood clot into circulation could result. During the flushing procedure, always aspirate for a brisk blood return from the catheter lumen.

If the catheter will not yield a blood return, further diagnostic studies may be needed to determine the cause of the problems. Thrombolytic agents such as alteplase (Cathflo Activase) may be used to dissolve blood clots in venous catheters (Genentech, 2011).

acceptable because these devices have mechanisms that prevent the backflow of blood into the catheter lumen.

For short peripheral catheters, usually 3 mL normal saline is adequate to flush the catheter. For all other catheters, 5 to 10 mL of preservative-free normal saline is needed. Bacteriostatic normal saline is limited to no more than 30 mL in a 24-hour period in adults. By using 10 mL before and after each dose of medication, it is easy to exceed this limitation. Check your agency's policy and procedure about specific flushing amounts.

Flush catheters immediately after each use. Delay in disconnecting the intermittent administration set and flushing the catheter could cause lumen occlusion from blood that backflows into the lumen when the infusion pressure is lower than venous pressure.

All fluids used to flush catheters should be obtained from single-dose containers or prefilled syringes. Vials used for multiple doses contribute to medication errors and increase the risk for contamination.

Obtaining Blood Samples from Central Venous Catheters

Short peripheral catheters should not be routinely used for obtaining blood samples. This additional manipulation could lead to vein irritation that requires removal of the catheter. Central venous catheters and midlines can be used for obtaining blood samples after a careful assessment of the risks versus the benefits. If your patient has no peripheral venipuncture sites or is fearful of needles, using the central venous catheter may be appropriate. The risks associated with obtaining blood samples from a central venous catheter are numerous. This procedure requires additional hub manipulation, which is a major cause of catheter-related bloodstream infection (CR-BSI). Consider the laboratory tests needed and the types of fluids that have recently been infused. Heparin interferes with coagulation studies. Electrolytes in the fluid may alter the results of serum electrolytes. Antibiotics such as vancomycin may interfere with measuring the peak serum levels of the drug. Drawing blood from catheters for blood culture should not be done within an hour of completion of antimicrobial infusions (Garcia & Isenberg, 2010).

If blood sampling from a central venous catheter is the best alternative, vigorous cleaning of the connections with 70% alcohol is necessary. Use methods that do not require needles. Vacuum tubes attached directly to the catheter hub eliminate the need to transfer the blood from a syringe into the tubes. For small-diameter catheters, the vacuum in the tube may cause the catheter to temporarily collapse, preventing the backflow of blood into the tube. In this situation, small syringes should be used because they create less pressure on aspiration, the opposite of what small syringes do on injection. Transfer of the blood from the syringe to the vacuum tube requires the use of a special transfer device to avoid the use of needles.

Removing the Vascular Access Device

Short peripheral catheters are usually removed 72 or 96 hours after insertion. If a complication develops, they should be removed immediately. Lift opposite sides of the transparent dressing and pull laterally to remove the dressing from the site while stabilizing the catheter. Slowly withdraw the catheter from the skin, and immediately cover the puncture site

with dry gauze. Do not use an alcohol pad because this will interfere with coagulation. Hold pressure on the site until hemostasis is achieved. Assess the catheter tip to make sure it is intact and completely removed. Document catheter removal and the appearance of the IV site.

Removal of midline catheters and PICCs must be performed with the same slow, gentle techniques used to insert the catheter. Veins can develop venospasms when rapid or forceful techniques are used. After explaining to the patient that this procedure will not be painful, remove the dressing and withdraw the catheter in short segments by pulling from the insertion site. *If you feel resistance, always stop and never apply force to the catheter. Extreme traction or force could cause the catheter to break and embolize to the heart or pulmonary circulation.*

Simple distraction techniques and deep breathing may be sufficient to relax the patient and remove the catheter. If these fail, replace the dressing and apply heat; allow time for the vein wall to relax. Keeping the extremity warm and dry and asking the patient to drink warm liquids could facilitate removal. Use of medications to relax the vein wall may be required if the catheter cannot be removed after several hours. Imaging studies may also be needed to determine whether the cause is a thrombosis instead of venospasm.

Nontunneled percutaneous central catheters are removed by clipping any sutures and withdrawing the catheter in short segments. Venospasm does not commonly occur when removing these catheters because the vein diameter is large.

For all catheters, immediately after the catheter comes out of the skin, apply digital pressure with a dry gauze dressing to stop any bleeding. Apply a sterile occlusive gauze dressing with an antiseptic ointment as per agency protocol or procedure. When a central venous catheter is removed, a tract between the skin and vein creates a conduit for air to be pulled into the vein. The ointment seals off the tract. After removal, measure the catheter length and compare it with the length documented on insertion. *If the entire catheter length was not removed, contact the health care provider immediately!*

Removal of tunneled catheters and implanted ports requires surgical techniques and is usually performed by nurse practitioners or physicians.

Documenting Intravenous Therapy

Nurses often are sued for malpractice related to infusion therapy, especially IV therapy. Therefore document after insertion of a vascular access device (VAD) and throughout the course of the therapy. When inserting a venous catheter, remember to document the:

- Date and time of the VAD insertion
- Name of the nurse (you) who inserted the VAD
- Vein that was used for insertion
- Type of VAD used
- Number of insertion attempts and locations of attempts before successful insertion
- Response of the patient to the VAD insertion process
- Type of dressing applied
- Type of securement device, if used
- Special barrier precautions used, if any
- Patient and family education provided related to IV therapy

During the course of the patient's infusion therapy, be sure to continue documenting your assessments and any interventions needed as a result of complications. Follow your agency's policies and procedures for additional requirements.

COMPLICATIONS OF INTRAVENOUS THERAPY

Complications from IV therapy can be minor and limited or life threatening. Serious life-altering or life-threatening complications are dramatically increasing in frequency and severity and present a tremendous financial burden to the U.S. health care system. Catheter-related bloodstream infections (CR-BSIs) are one of the most serious problems, often resulting in patient death. They are more common in patients with central VADs than with peripheral catheters.

Catheter-Related Bloodstream Infection

The Institute for Healthcare Improvement identified catheter-related bloodstream infections (CR-BSI) as one of several preventable hospital-acquired infections (HAIs). They report that CR-BSIs are responsible for up to 28,000 deaths per year, and as part of their previous *100,000 Lives Campaign*, a number of evidence-based interventions were combined into the CR-BSI prevention bundle. As a nurse, your accountability is to ensure that these interventions are followed. The most common tool used to improve adherence is a memory checklist. Tell anyone who violates the following interventions to stop the procedure immediately.

Hand hygiene before inserting a central line must be thorough (i.e., no quick scrub). Anyone who touches the central line must also perform thorough hand hygiene. *Maximal barrier precautions* during line insertion require that the patient be draped from head to toe with a sterile barrier. The practitioner who inserts the VAD wears sterile gloves, gown, and mask. Anyone in the room during the procedure must also wear a mask, and traffic in and out of the room must be minimized. Chlorhexidine is used for skin disinfection because it has best outcomes for preventing infection. For infection control, subclavian sites are the most *appropriate sites* and are preferable to internal jugular and upper arm veins. PICC lines are preferable to subclavian vascular access devices (VADs). *Post-placement care* requires meticulous dressing changes and care of all parts of the IV system, such as keeping ports and stopcocks clean and hanging bags using sterile technique. Review daily the need for the patient's VAD. The incidence of CR-BSI increases each day the device is in place. As soon as it is determined that the patient no longer needs the IV line, it should be removed (*Institute for Healthcare Improvement [IHI], 2008*).

Other Complications of Intravenous Therapy

Local complications of IV therapy occur at or near the catheter. A priority for care for patients with IV therapy is to prevent, assess, and detect these complications. In some cases, nurses also manage these problems. Definitions, causes, signs and symptoms, treatment, and prevention of local complications are summarized in [Table 15-2](#). *Systemic complications* of IV therapy involve the entire vascular system or multiple systems. Information on common systemic complications can be found in [Table 15-3](#). For central venous catheters

(CVCs), complications can occur during the insertion procedure or during the dwell time; these problems are described in [Tables 15-4 and 15-5](#). [Tables 15-6 and 15-7](#) are the INS criteria for grading phlebitis and infiltrations. Document all assessments and complications in the patient's health record. Notify the infusion therapy team and/or health care provider per agency policy when complications occur.

IV THERAPY AND CARE OF THE OLDER ADULT

The aging process causes numerous changes in all body functions, and yet aging occurs differently in each person. Nutrition, environment, genetics, social factors, and education are just a few of the factors that influence the older adult's needs. Because all body functions are affected, IV therapy can be affected by these changes.

Skin Care

Aging skin becomes thinner and loses subcutaneous fat, decreasing the skin's ability for thermal regulation. Fewer nerve endings mean the decreased ability to feel pain. Older patients *may* not perceive pain from traumatic venipuncture requiring excessive probing or multiple attempts. However, this action increases the risk for fluid leakage and subsequent infiltration or extravasation injury. Inserting and removing a catheter and dressing could tear the skin layers.

Skin antisepsis is extremely important because of the decreased immunity seen as part of the aging process. Lipids are normally found in skin as a protective agent, and alcohol easily dissolves lipids. Although greater numbers of organisms may be killed, the skin can also become excessively dry and cracked. Current recommendations call for using friction when cleaning the skin to penetrate the layers of the epidermis. However, excessive friction may damage fragile skin. Chlorhexidine is now the preferred agent, and the product currently available contains alcohol. Check for allergies to iodine before using iodine or iodophors. Iodophors such as povidone-iodine require contact with the skin for a minimum of 2 minutes to be effective. All antiseptic solutions must be thoroughly dry before applying the dressing or tape.

Skin should never be shaved before venipuncture, but excessive amounts of hair should be clipped. Shaving causes micro-abrasions that can lead to infection. The skin of an older adult may be more delicate and therefore more easily nicked while shaving.

Skin integrity can easily be compromised by the application of tape or dressings. Use of skin protectant solutions puts a protective barrier between the skin and dressing and improves the adherence of the dressing to the skin. Removal of tape and dressings may require adhesive remover solutions, or an alcohol pad may accomplish the same purpose. Securement devices like the StatLock require the use of a skin protectant (e.g., Skin-Prep) before applying the device. The protectant prevents skin tearing when the device is removed.

Vein and Catheter Selection

Vein and catheter selection are of highest importance in older adults. Choose insertion sites carefully after consideration of the patient's skin integrity, vein condition, and functional ability. The general principle of starting with the most distal

TABLE 15-2 LOCAL COMPLICATIONS OF INTRAVENOUS THERAPY

COMPLICATION	CAUSE	SIGNS AND SYMPTOMS	TREATMENT	PREVENTION
Infiltration				
Leakage of a non-vesicant IV solution or medication into the extravascular tissue	Peripheral catheter has punctured opposite vein wall Obstruction of blood flow causing backflow through original entrance site Inflammatory process causing fluid leakage at the capillary level Fibrin sheath fully encasing a central venous catheter leading to retrograde flow and leakage from venipuncture site Damaged septum of implanted port Dislodged port access needle	IV rate slows Increasing edema around site Patient report of skin tightness; blanching or coolness of skin; burning, tenderness, or general discomfort at the insertion site; fluid leaking from puncture site; absence of a blood return (though this may not be reliable with a short peripheral catheter)	Stop infusion and remove short peripheral catheter immediately after identification of problem. Apply sterile dressing if weeping from tissue occurs. Elevate extremity. Warm or cold compresses may be used according to the solution infiltrated and organizational policy. Warm compresses increase circulation to the area and speed healing. Cool compresses may be used to relieve discomfort and reduce swelling. Insert a new catheter in the opposite extremity. For all central venous catheters, obtain a study to determine the cause of the problem. For implanted port, remove and insert a new port access needle. Rate the infiltration using the INS Infiltration Scale and document (Table 15-7).	Catheter stabilization—use smallest catheter appropriate; avoid area of flexion, or use arm board. Avoid placing restraints at the IV site. Make successive venipunctures proximal to the previous site. Monitor site frequently; educate patient about activities and signs and symptoms. Central venous catheters—obtain a brisk blood return before using the catheter for infusion. Frequently assess proper positioning of port access needle. Stabilize it well, and protect from clothing.
Extravasation				
Leakage of a vesicant IV solution or medication into the extravascular tissue This can occur with both peripheral and central catheters	Same as infiltration	Same as infiltration Blistering and tissue sloughing may not appear for a few days and resolves over 1-4 wk with infiltration of some chemotherapeutic agents such as anthracycline and alkylating agents	Stop infusion, and disconnect administration set. Aspirate drug from short peripheral catheter or port access needle. Leave short peripheral catheter or port access needle in place to deliver antidote, if indicated by established policy. If possible, aspirate residual drug from the exit site of a central venous catheter. Administer antidote according to established policy. Apply cold compresses for all drugs EXCEPT vinca alkaloids and epipodophyllotoxins. Photograph site. Monitor at 24 hr, 1 wk, 2 wk, and as needed. Surgical interventions may be required. Provide written instructions to patient and family.	Same as infiltration. Know the vesicant potential before giving any IV medication. Prevention is key.
Phlebitis				
Inflammation of the vein Post-infusion phlebitis presents within 48-96 hr after the catheter has been removed	Mechanical cause from insertion technique, catheter size, and lack of catheter securement Chemical cause from extremes of pH and/or osmolality of the fluid or medication Bacterial cause from a break in aseptic technique, poor securement, and extended dwell time	Patient may report pain at the IV site; nurse may observe that vein appears red and inflamed along the length; vein may become hard and cordlike (Table 15-6)	Remove short peripheral catheter at the first sign of phlebitis; use warm compresses to relieve pain. Monitor frequently. Document using Phlebitis Scale. Insert a new catheter using the opposite extremity. Mechanical phlebitis occurring in the first week after PICC insertion may be treated without catheter removal. Apply continuous heat; rest and elevate the extremity. Significant improvement is seen in 24 hr, and complete resolution is seen within 72 hr. Remove catheter if treatment is unsuccessful.	Choose the smallest-gauge catheter for the required therapy. Avoid sites of joint flexion, or stabilize with an armboard. Avoid infusing fluids or medications with a pH below 5 or above 9 through a peripheral vein. Avoid infusing fluids or medications with a final osmolality above 500 mOsm/L through a peripheral vein. Rotate sites every 72-96 hr according to established policy. Adequately secure the catheter. Use aseptic technique. For PICCs, teach patient to avoid excessive physical activity with the extremity.

Thrombosis

Blood clot inside the vein

Anything that damages the endothelial lining of the intima can initiate clot formation	Slowed or stopped infusion rate	Stop infusion and remove short peripheral catheter immediately.	Use evidence-based venipuncture technique. Make only two attempts to perform venipuncture. Choose the smallest-gauge catheter in the largest vein possible.
Traumatic venipuncture	Swollen extremity	Apply cold compresses to decrease blood flow and stabilize the clot.	Secure catheter adequately.
Multiple venipuncture attempts	Tenderness and redness	Elevate extremity.	Use armboards if short peripheral catheters are placed in areas of joint flexion.
Use of catheters too large for the chosen vein	Engorged peripheral veins of the ipsilateral chest and extremity	Surgical intervention may be required.	Ensure adequate hydration to avoid changes in blood composition and flexion of the extremity.
Hyper-coagulable state and venous stasis		For central venous catheters, notify the physician and obtain requests for a diagnostic study. Low-dose thrombolytic agents can be used to lyse the clot.	Prophylactic low-dose warfarin (Coumadin, Warfilone 🍷) may be prescribed for patients with a central venous catheter.

Thrombophlebitis

The presence of a blood clot and vein inflammation

Same as phlebitis and thrombosis

Same as phlebitis and thrombosis.

Apply cold compresses initially, followed by warm.

Echymosis and Hematoma

Echymosis from infiltration of blood into the surrounding tissue
Hematoma results from uncontrolled bleeding

Unskilled or multiple attempts
Patients with coagulopathy or fragile veins (e.g., older adults and patients on steroids)
Accidental laceration of a large vein or artery

When removing device, apply light pressure, excessive pressure could cause other fragile veins in the area to rupture.
For hematoma, apply direct pressure until bleeding has stopped. Elevate extremity, apply ice for first 24 hours, then warm compress for comfort.

Avoid veins that cannot be easily seen or palpated.
Use extra caution in patients with coagulopathies.
Use good venipuncture technique.

Site Infection

Invasion of microorganisms at the insertion site in the absence of simultaneous bloodstream infection
Infection localized at the insertion site, the port pocket, or subcutaneous tunnel

Clean exit site with alcohol, expressing drainage if present.
For short peripheral catheter, midline catheter, or PICC, remove using sterile technique and avoid contact between skin and catheter.
Send catheter tip for culture, if requested.
Clean site with alcohol, and cover with dry sterile dressing; physician to evaluate for septic phlebitis and need for antimicrobial therapy or surgical intervention.

Use strict aseptic technique when inserting, maintaining, or removing catheters.
Practice good hand hygiene.
Ensure dressing remains clean, dry, and adherent to skin at all times.

Venous Spasm

A sudden contraction of the vein

A normal response to irritation or injury of the vein wall

Cramping or pain at or above the insertion site
Numbness in the area
Slowing of the infusion rate
Inability to withdraw midline catheter or PICC

Allow time for vein diameter to return to normal after tourniquet removal and before advancing catheter.
Infuse fluids at room temperature, if possible.
For a midline catheter or PICC, gently withdraw the catheter in short segments.

Nerve Damage

Inadvertent piercing or complete transection of a nerve

Venipuncture near known nerve locations
Unanticipated nerve locations

Reports of tingling or feeling “pins and needles” at or below the insertion site
Numbness at or near the insertion site

Avoid using the cephalic vein near the wrist.
Avoid using veins on the palm side of the wrist.
Adequately secure the catheter, but avoid tape that is too tight.
Support areas of joint flexion with an armboard.

TABLE 15-3 SYSTEMIC COMPLICATIONS OF INTRAVENOUS THERAPY

COMPLICATION	CAUSE	SIGNS AND SYMPTOMS	TREATMENT	PREVENTION
Circulatory Overload				
Disruption of fluid homeostasis with excess fluid in the circulatory system	Infusion of fluids at a rate greater than the patient's system can accommodate	Patient may report shortness of breath and cough; patient's blood pressure is elevated, and there is puffiness around the eyes and edema in dependent areas; patient's neck veins may be engorged, and nurse may hear moist breath sounds.	Slow the IV rate, and notify physician; raise patient to an upright position; monitor vital signs, and administer oxygen as prescribed; administer diuretics as prescribed.	Monitor intake and output carefully, and notify physician as soon as an imbalance is noticed between the patient's intake and output.
Speed Shock				
Systemic reaction to the rapid infusion of a substance unfamiliar to the patient's circulatory system	Rapid infusion of drugs or bolus infusion, which causes the drug to reach toxic levels quickly	Patient may report lightheadedness or dizziness and chest tightness; nurse may note that patient has a flushed face and an irregular pulse; without intervention, patient may lose consciousness and go into shock and cardiac arrest.	Immediately discontinue the drug infusion and hang isotonic solution to keep the vein open; monitor vital signs carefully, and notify physician for further treatments.	Be aware of the appropriate infusion rate of medications and adhere to them; use of infusion control devices assists in prevention of speed shock.
Catheter Embolism				
A shaving or piece of catheter breaks off and floats freely in the vessel	Anything that damages the catheter—during insertion, dressing change, excessive force with flushing or medication administration	Depending on where the catheter embolizes, this could be life threatening Cardiopulmonary arrest could occur.	Emergently notify the physician. Remove the catheter, and apply a tourniquet high on the limb of the catheter site; inspect catheter to determine how much may have embolized; an x-ray is taken to determine the presence of any catheter piece; surgical intervention may be necessary.	When inserting over-the-needle catheters, never reinsert the needle into the catheter; avoid pulling a through-the-needle catheter back through the needle during insertion. Avoid scissors near the catheter with dressing changes.

sites usually indicates use of hand veins. *However, avoid fragile skin and small, tortuous veins on the back of the hand (dorsum); select the initial IV site higher on the arm.*

Venous distention must be accomplished with a flat tourniquet; however, the veins may require longer to distend adequately. Allowing a tourniquet to remain in place for extended periods causes an overfilling of the vein and can result in a hematoma when the vein is punctured. On extremely fragile skin, the tourniquet application can lead to ecchymotic areas or skin tears. A tourniquet may not be required in veins that are already distended; however, carefully palpate these veins to determine their condition. Avoid hard, cordlike veins. Blood pressure cuffs can also be used for venous distention. Inflate the cuff and release until the pressure is slightly less than diastolic pressure. Other methods to distend veins include:

- Tapping lightly, but avoiding forceful slapping
- Asking the patient to open and close the fist so the muscles can force blood into the veins, making sure the hand is relaxed when the venipuncture is attempted
- Placing the extremity lower than the heart
- Applying heat to the entire extremity for 10 to 20 minutes and removing just before making the venipuncture

As with all patients, venipuncture technique requires adequate skin and vein stabilization during the puncture and complete catheter advancement. Veins of an older adult are more likely to roll away from the needle. Low angles of 10 to

15 degrees between the skin and catheter will improve your success with venipuncture.

As soon as the catheter enters the vein, it may be necessary to release the tourniquet. Release of venous pressure from the puncture can lead to ecchymosis. Allowing the tourniquet to remain in place during the complete catheter advancement could increase this problem.

! NURSING SAFETY PRIORITY

Action Alert

Catheter securement may mean that administration sets are placed out of easy reach of a confused patient. Use flexible netting over the extremity to help prevent the patient from pulling at the dressing or tubing, while allowing easy access to the site. A device such as the I.V. House UltraDome shown in Fig. 15-15 can also protect the site. Do not use rolled bandages to cover the extremity because they prevent insertion site assessment. Complications may progress to an advanced state before they are noticed.

Choosing a midline catheter or PICC may be best in older patients with poor skin turgor, limited venous sites, or veins that are fragile, tortuous, or hard. These catheters are placed in the upper extremity where venous distention techniques can be used. Inserting nontunneled percutaneous central catheters in older adults can be much more challenging. Venous distention for insertion requires the Trendelenburg position and a well-hydrated patient. Fluid volume deficit

TABLE 15-4 INSERTION-RELATED COMPLICATIONS OF CENTRAL VENOUS CATHETERS

COMPLICATION	CAUSE	SIGNS AND SYMPTOMS	TREATMENT	PREVENTION
Pneumothorax Collection of air in the pleural space	Puncture of the pleural covering of the lung by the introducer on insertion of a direct subclavian approach	Chest pain Dyspnea Apprehension Cyanosis Decreased breath sounds on the affected side Abnormal chest x-ray findings	Remove catheter, or assist with removal. Assess patient by monitoring vital signs, and assess breath sounds. Notify physician immediately if suspected after insertion. Administer oxygen as prescribed. Assist with insertion of a chest tube.	Use jugular or upper extremity insertion sites instead of subclavian sites. Use ultrasound to locate veins.
Hemothorax Collection of blood in the pleural cavity	Result of puncture or transection of the subclavian vein or artery	Similar to pneumothorax; usually see dyspnea first and then tachycardia Decreased hemoglobin because of blood pooling	Same as for pneumothorax. Apply pressure on insertion site after introducer needle and catheter are removed.	Use jugular or upper extremity insertion sites instead of subclavian sites. Use ultrasound to locate veins.
Chylothorax Lymph (chyle) enters the pleural cavity	Transection of the thoracic duct on the left side	Same as in hemothorax Usually noted on insertion with withdrawal of a milklike substance	Same as for pneumothorax.	Use right side for subclavian insertion. Use jugular or upper extremity insertion sites. Use ultrasound to locate veins.
Hydrothorax Infusion of IV fluids directly into the thoracic cavity	Transection of the subclavian vein and placement of the catheter into the thoracic cavity	Same as in pneumothorax with absence of vesicular breath sounds and a murmur with a flat sound over the location	Same as for pneumothorax with removal of the catheter and aspiration of fluid.	Use jugular or upper extremity insertion sites instead of subclavian sites. Use ultrasound to locate veins.
Air Embolism Air enters the central venous system through the catheter when the intrathoracic pressure is lower than the atmospheric pressure and the catheter provides an open conduit for the air	Air introduced into the central venous system during catheter insertion, accidental disconnection of tubing, tubing changes, catheter rupture, and catheter removal	Chest pain, dyspnea, hypoxia Anxiety, tachycardia, hypotension Nausea Light-headed, dizzy Loud churning heard over the pericardium on auscultation is possible but not always heard	Clamp catheter immediately. Place patient in left lateral Trendelenburg position. Notify physician immediately. Oxygen therapy. Arterial blood gases. Electrocardiogram.	Prevent inadvertent disconnection. Use Luer-Lok needleless connector caps. Close slide clamp on catheter extension when changing connector caps. When inserting or removing catheter, prevent negative intrathoracic pressure by placing the patient flat and having him or her perform a Valsalva maneuver or hold his or her breath if possible. Apply occlusive dressing with antiseptic ointment when removing a central venous catheter; allow to remain in place for at least 24 hr.
Arterial Puncture Laceration of an artery	Accessed the artery instead of the vein	Pulsating of bright red blood from the introducer needle	Remove needle immediately, and apply pressure to the site. Secure a pressure dressing for 5-10 min.	Use ultrasound to locate veins during insertion procedure.
Malpositioned Catheters Catheter has passed into the jugular vein, the right atrium, the azygos vein, or several other tributary veins	Improper patient positioning during insertion Insertion of catheter length that is too short or too long for patient	No signs or symptoms may be experienced before detection on initial chest radiograph to confirm tip location Ear, neck, or back pain Palpitations or dysrhythmias Inability to irrigate	Notify physician to reposition catheter by guidewire exchange. Refer to radiology for replacement under fluoroscopy.	Insert under fluoroscopy. Ensure proper patient measurement for catheter length. Position patient properly.

TABLE 15-5 COMPLICATIONS DURING THE DWELL OF CENTRAL VENOUS CATHETERS

COMPLICATION	POSSIBLE CAUSES	SIGNS AND SYMPTOMS	TREATMENT	PREVENTION
Catheter Migration				
Movement of a properly placed catheter tip to another vein	Changes in intrathoracic pressure caused by coughing, vomiting, sneezing, heavy lifting, and congestive heart failure	For migration to the jugular vein: reports of hearing a running stream or gurgling sound on the side of catheter insertion For migration to the azygos vein: back pain between the shoulder blades Neurologic complications if medications are infused	Stop all infusions, and flush catheter. Notify physician. Obtain a chest radiograph to assess tip location. Spontaneous repositioning back to the SVC is possible. Repositioning by radiology may be required.	Place catheter tip properly in the lower third of the SVC near the junction with the right atrium. Instruct patient to perform usual ADLs but to avoid excessive physical activity.
No change in the external catheter length				
Catheter Dislodgment				
Movement of catheter into or out of the insertion site	Inadequate catheter securement Excessive physical activity with a PICC	External catheter length has changed, also changing the internal tip location No other signs or symptoms may be immediately noticed	Stop all infusions, and flush catheter. NEVER re-advance the catheter into the insertion site. Determine the amount of external catheter length, and compare with the length documented on insertion. Notify the physician or nurse inserting the catheter for further assessment.	Proper catheter securement. Instruct patient to perform normal ADLs but to avoid excessive physical activity.
Catheter Rupture				
Catheter is broken, damaged, or separated from hub or port body	Forcefully flushing a catheter with any size syringe against resistance Using scissors to remove a dressing Catheter compression of a subclavian inserted catheter between the clavicle and first rib (also known as <i>pinch-off syndrome</i>)	Fluid leaking from insertion site Pain or swelling during infusion Reflux of blood into the catheter extension Inability to aspirate blood from catheter	Repair the damaged segment; depends on the availability of a repair kit designed for the specific brand of catheter being used; repair may be considered a temporary measure instead of a permanent treatment. Remove catheter.	NEVER use excessive force when flushing a catheter, regardless of syringe size. On injection, small syringes generate more pressure than larger syringes. Use of a 10-mL syringe is generally recommended for flushing procedures. Insert catheter through jugular or upper extremity sites instead of subclavian site.
Lumen Occlusion				
Catheter lumen is partially or totally blocked	Drug or mineral precipitate (calcium, diazepam, and phenytoin are common) Lipid sludge from long-term infusion of fat emulsion Blood clots and fibrin sheath caused by blood reflux into lumen Allowing administration sets to remain connected for extended periods after medication has infused	Infusion stops or pump alarm sounds Inability or difficulty administering fluids Inability or difficulty drawing blood Increased resistance to flushing of the catheter	Assess history of catheter use. A suddenly developing problem may indicate contact between incompatible medications. A problem that develops over an extended period may indicate a gradual clot formation. For drug precipitate, determine the pH of the precipitated drug. Use hydrochloric acid for acidic drug. Use sodium bicarbonate for alkaline drugs. For blood clot, use thrombolytic enzymes such as alteplase.	Always flush with normal saline between, before, and after each medication given through the catheter. Use positive-pressure flushing techniques when a negative fluid displacement needleless connector is being used. Use a positive fluid displacement needleless connector. Flush catheters immediately when medication infusion is complete.
Central Line–Related Bloodstream Infection (CR-BSI)				
Pathogenic organisms invade the patient's circulation The CDC has specific criteria to classify these infections	Lack of sterile field during insertion Inadequate skin antiseptic agents and application techniques Manipulation of the catheter hub leading to intraluminal contamination Inadequate hand hygiene Long dwell time	Early symptoms include fever, chills, headache, and general malaise	Change the entire infusion system from solution to IV device; notify physician, obtain cultures, and administer antibiotics as prescribed. If the infusate is the suspected cause, send a specimen to the laboratory for evaluation.	Maintain sterile technique. Use the recommended CR-BSI prevention bundle.

FIG. 15-15 I.V. House UltraDressing IV site protector, a safety device used for IV site protection, guards the integrity of the older adult's skin while helping secure the site.

TABLE 15-6 PHLEBITIS SCALE FROM INS STANDARDS OF PRACTICE

GRADE	CLINICAL CRITERIA
0	No symptoms
1	Erythema with or without pain
2	Pain at access site with erythema and/or edema
3	Pain at access site with erythema and/or edema Streak formation Palpable cord
4	Pain at access site with erythema and/or edema Streak formation Palpable venous cord more than 1 inch long Purulent drainage

Data from Infusion Nurses Society (INS). (2006). Infusion nursing standards of practice. *Journal of Infusion Nursing*, 29(1 Suppl. 6S), S1-S92.

prevents adequate distention of the subclavian or jugular veins. Patients with conditions like chronic obstructive pulmonary disease and kyphosis cannot tolerate the Trendelenburg position. Tunneled catheters and implanted ports may be appropriate after consideration of the surgical techniques required to insert these catheters.

Cardiac and Renal Changes

Because of changes in cardiac and renal status, the accuracy of infusion volume and flow rate measurements is very important in the older adult. The health care provider's prescription for infusion therapy should be assessed for appropriateness for the patient's condition. Older adults are very prone to fluid overload and resulting congestive heart failure. Electronic controlling devices may be required to ensure the necessary accuracy. Clinical manifestations of fluid overload are described in [Chapter 13](#).

TABLE 15-7 INFILTRATION SCALE FROM INS STANDARDS OF PRACTICE

GRADE	CLINICAL CRITERIA
0	No symptoms
1	Skin blanched Edema <1 inch in any direction Cool to touch With or without pain
2	Skin blanched Edema 1-6 inches in any direction Cool to touch With or without pain
3	Skin blanched, translucent Gross edema >6 inches in any direction Cool to touch Mild to moderate pain Possible numbness
4	Skin blanched, translucent Skin tight, leaking Skin discolored, bruised, swollen Gross edema >6 inches in any direction Deep pitting tissue edema Circulatory impairment Moderate to severe pain Infiltration of any amount of blood product, irritant, or vesicant

Data from Infusion Nurses Society (INS) (2006). *Standards of Practice*, Norwood, MA.

DECISION-MAKING CHALLENGE

Patient-Centered Care; Teamwork and Collaboration; Informatics

A 75-year-old woman is transferred from the local community hospital to the skilled nursing facility (SNF) where you work as a charge nurse. The resident is being managed with IV cefazolin 2 g IVPB every 8 hours for right ankle osteomyelitis resulting from an arterial ulcer. On review of her admission orders, you note that she has a newly-inserted intermittent saline lock in her right forearm and is prescribed to receive the antibiotic for 6 more weeks.

1. The SNF policy for administration of drugs prescribed every 8 hours is a 6 PM-2 AM-10 AM schedule. Would you schedule her antibiotic at these times? Why or why not?
2. The resident states that she has not had a bath in 5 days and wants to take a shower. Will she be allowed to take a shower? Why or why not?
3. Two days later as you are planning to end your shift, the resident reports that her IV site seems swollen. What action will you take at this time? What will you document on the resident's medical record?
4. Is a peripheral vascular access device (VAD) the best choice for this resident? Why or why not? With whom will you or the oncoming nurse collaborate to make this decision? What does the evidence say about the type of VAD that would be best to meet this resident's needs? Where would you go to find the answer to this clinical question?
5. Using the SBAR technique, what will you report to the oncoming nurse about the resident's IV complications?

When fluid restrictions are required, medications could be diluted in small quantities and delivered using a syringe pump or a manual IV push. For instance, 1 g of an antibiotic could be diluted in 10 mL normal saline instead of the more common 50 mL. This alternative allows the patient to have

more fluid to drink. Serum sodium levels should be considered when normal saline is routinely used for dilution in patients with hypertension or cardiac problems.

For a poorly controlled diabetic patient, dextrose solutions for dilution may not be preferred, although well-controlled diabetic patients may not have a problem with the small amount of dextrose in the solution. Consult with the pharmacist and prescriber to answer these questions.

ALTERNATIVE SITES FOR INFUSION

An increasing number of patients with chronic illness require repeated and frequent IV therapies. Many of these patients are vein depleted and need vein preservation. Subcutaneous and intraosseous routes have demonstrated effectiveness in emergency resuscitation. These procedures may also be beneficial for routine infusion of isotonic, non-irritant, non-vesicant solutions in patients with chronic illness and vein depletion (Aguilar, 2010).

Specific therapies requiring infusion into arteries, peritoneum, epidural, and intrathecal space are also available. These therapies are most commonly used to administer chemotherapy, lytic therapy, or pain medication.

Subcutaneous Infusion

Subcutaneous therapy may be used in palliative care patients who cannot tolerate oral medications, when IM injections are too painful, or when vascular access is not available or is too difficult to obtain. Most often, this type of infusion is used in hospices for pain management.

Hypodermoclysis involves the slow infusion of isotonic fluids into the patient's subcutaneous tissue. Although common in the early twentieth to mid-twentieth century, this method had not been widely used again until the 1990s. The growth of geriatric and palliative health care has helped spur the use of this method of infusion therapy for selected patients (Khan & Younger, 2007).

Hypodermoclysis can be used for short-term fluid volume replacement. The patient must have sufficient sites of intact skin without infection, inflammation, bruising, scarring, or edema. The most common sites are the front and sides of the thighs and hips, the upper abdomen, and the area under the clavicle. Unlike IV therapy, the upper extremities should not be used because fluid is absorbed more readily from sites with larger stores of adipose tissue. Hypodermoclysis should not be used if the fluid replacement needs exceed 2000 to 3000 mL/day, in emergency situations, or if there are bleeding or coagulation problems (Khan & Younger, 2007).

Hyaluronidase 150 units may be mixed with each liter of infusion fluid. This is an enzyme that improves the absorption of the infusing fluids from the subcutaneous tissue. An intradermal test dose is required because of the possibility of an allergic reaction. If the enzyme is not used, the infusion may not be well absorbed and redness at the insertion site is more likely (Khan & Younger, 2007).

A small-gauge, winged infusion or "butterfly" needle, a small-gauge, short peripheral catheter, or an infusion set specially designed for subcutaneous infusion can be chosen. The subcutaneous infusion sets have a small needle extending at a right angle from a flat disk that helps stabilize the needle.

When choosing the infusion site, consider the patient's level of activity. The area under the clavicle or the abdomen

may interfere the least with ambulation. Clip excess hair in the area, and clean the chosen site with the antiseptic solution, preferably chlorhexidine gluconate. Prime the infusion tubing and the attached subcutaneous infusion set or winged needle. Gently pinch an area of about 2 inches (5 cm), and insert the needle using sterile technique. After securing the needle, cover the site with a transparent dressing. Hydrocortisone cream can be applied to the skin to prevent irritation.

Flow rates for hydration fluids begin at 30 mL/hr. After 1 hour, the rate can be increased if the patient has experienced no discomfort. The maximum rate is usually 75 to 80 mL/hr. For pain medication infusion, the flow rate is usually 2 or 3 mL/hr. If the infusion is required for adequate pain control, two subcutaneous sites may be needed.

Assess the site at least twice daily. Redness, heat, leakage, bruising, swelling, and reports of pain indicate tissue irritation, and the infusion needle should be removed. Rotate the subcutaneous site at least once per week.

Other complications include pooling of the fluid at the insertion site and an uneven fluid drip rate. Both of these problems may be resolved by restarting the infusion in another location. An infusion pump may also be used. Small ambulatory infusion pumps can be used to allow for greater mobility.

Intraosseous Therapy

Description

Intraosseous (IO) therapy allows access to the rich vascular network in the red marrow of bones. Although IO has previously been regarded as a pediatric procedure, it is now considered acceptable for use in adults. Victims of trauma, burns, cardiac arrest, diabetic ketoacidosis, and other life-threatening conditions benefit from this therapy because often clinicians cannot access these patients' vascular systems for traditional IV therapy (Aguilar, 2010). Intraosseous catheters may be established in the prehospital setting when IV access cannot be readily obtained in an emergency.

Absorption rates of large-volume parenteral (LVP) infusions and drugs administered via the IO route are similar to those achieved with peripheral or central venous administration. The IO route should be used only during the immediate period of resuscitation and should not be used longer than 24 hours (Aguilar, 2010). After establishing access, efforts should continue to obtain IV access as well.

There are few contraindications for intraosseous infusion. The only absolute contraindication is fracture in the bone to be used as a site. Conditions such as severe osteoporosis, osteogenesis imperfecta, or other conditions that increase the risk for fracture with insertion of the IO needle and skin infection over the site may also be contraindications for some patients. Repeated attempts to access the same site should be avoided (Madigan, 2008).

Any needle could be used to provide therapy and access the medullary space (marrow). However, 15- or 16-gauge needles specifically designed for IO are preferred because they have:

- A removable stylet that screws into the cannula to keep the needle from retracting during insertion
- A short shaft to eliminate accidental dislodgment after placement
- An adjustable guard to stabilize the needle at skin level

FIG. 15-16 Proximal tibial intraosseous (IO) access.

- Graduations along the needle to guide the practitioner during insertion

New technology using a battery-powered drill has improved the ease of IO insertion. A number of sites can be used, including the proximal tibia, distal femur, medial malleolus (inner ankle), proximal humerus, and iliac crest. The proximal tibia is the most common site accessed for IO therapy (Fig. 15-16).

Nursing Care

If IV access cannot be obtained within the first few minutes of resuscitation procedures, IO may be attempted. The leg is restrained, and the site is cleaned with an antiseptic agent such as chlorhexidine. After successful insertion, the needle must be secured to prevent movement out of the bone. The same doses of fluids and medications can be infused IO as IV. An infusion pump may be used for rapid flow rates.

During the procedure, most patients rate the pain as a 2 or 3 on a scale of 0 to 10. Lidocaine 1% is used to anesthetize the skin, the subcutaneous tissue, and the periosteum to promote comfort (Madigan, 2008).

Improper needle placement with infiltration into the surrounding tissue is the most common complication of IO therapy. An accumulation of fluid under the skin at either the insertion site or on the other side of the limb indicates that the needle either is not far enough in to penetrate the bone marrow or is too far into the limb and has protruded through the other side of the shaft. Needle obstruction occurs when the puncture has been accomplished but flushing has been delayed. This delay may cause the needle to become clotted with bone marrow.

Osteomyelitis is an unusual but serious complication of IO therapy. It is caused by allowing the IO needle to remain in place for a prolonged period.

Compartment syndrome is a condition in which increased tissue pressure in a confined anatomic space causes decreased blood flow to the area. The decreased circulation to the area leads to hypoxia and pain in the area. Although the complication is rare in IO therapy, the nurse should monitor the site carefully and alert the physician promptly if the patient exhibits any signs of decreased circulation to the limb, such as coolness, swelling, mottling, or discoloration. Without improvement in perfusion to the limb, the patient could ultimately require amputation of the limb. Nursing assessment and interventions for compartment syndrome are discussed in detail in Chapter 54.

Intra-arterial Therapy

Description

Catheters are placed into arteries to obtain repeated arterial blood samples, to monitor various hemodynamic pressures continuously, and to infuse chemotherapy agents. Catheters placed in the radial, brachial, or femoral arteries are used for obtaining blood samples or arterial pressure monitoring. Pulmonary artery pressure measures the function of the left heart and is accomplished by advancing a catheter through the central venous system, through the right heart chambers, and into the pulmonary artery (hemodynamic monitoring).

Catheters used for pressure monitoring are inserted percutaneously through veins of the upper extremity or the subclavian or jugular sites. Insertion procedures are similar to the procedures used for venous cannulation. Removal requires deflating arterial balloons, if used, and applying digital pressure for longer than when removing a venous catheter to prevent a significant hematoma from forming.

Arterial waveforms and pressures are converted to digital values displayed on attached monitors. Between the catheter and the monitor is a special administration set capable of handling high infusion pressure, a pressurized fluid container, a continuous flush attachment, a three-way stopcock, and a transducer. In the past, it was common to use a heparinized saline flush solution in the pressurized fluid container. Studies have shown that this solution increases the risk for heparin-induced thrombocytopenia, and the use of heparin is now generally avoided (Swanson, 2007). The transducer is positioned at the level of the patient's atrium and secured to an IV pole to enable correct arterial pressure measurements. Hemodynamic monitoring and how to interpret these values are described in Chapter 35.

Chemotherapy agents administered arterially allow infusion of a high concentration of drug directly to the tumor site before it is diluted in blood or metabolized by the liver or kidneys. Drug infusion through the same blood supply

feeding the tumor optimizes cell destruction at the tumor site while minimizing systemic side effects. The most common arterial sites include the hepatic and celiac arteries for liver tumors, although the carotid artery for tumors of the head, neck, or brain and pelvic arteries for cervical tumors have been used.

Arterial catheter insertion can be performed percutaneously, via a surgical procedure, or through an interventional radiologic procedure. Implanted ports are commonly used for extended therapies. For short-term therapy, an external catheter may be used for 3 to 7 days, although the risks for complications increase during dwell time.

Another device used for arterial infusion of chemotherapy agents is an implanted pump with an attached catheter. This small device holds 50 mL of fluid in an upper chamber. The lower chamber exerts pressure when the upper chamber is filled, causing the drug to flow at 1 to 2 mL/day. Changes in blood pressure, body temperature, and altitudes alter the flow rate. The patient must return for refilling the fluid chamber every 14 days.

NURSING SAFETY PRIORITY

Critical Rescue

Carefully secure all junctions on the administration sets with Luer-Lok devices. Life-threatening hemorrhage can occur if an accidental disconnection occurs! When an infusion pump is used, be sure that it had a pressure high enough to overcome arterial pressure. Closely monitor the arterial insertion site and affected extremity. Assess the extremity for warmth, sensation, capillary refill, and pulse.

Nursing Care

When the carotid artery is involved, perform neurologic assessments. When a femoral catheter is used, apply anti-embolic stockings or other measures to prevent deep vein thrombosis.

Complications from arterial catheters are similar to those from venous catheters, including infection, bleeding from the insertion site, hemorrhage from a catheter disconnection, catheter migration, infiltration, and catheter lumen or arterial occlusion.

Intraperitoneal Infusion

Intraperitoneal (IP) therapy is the administration of chemotherapy agents into the peritoneal cavity. IP therapy is used to treat intra-abdominal malignancies such as ovarian and gastrointestinal tumors that have moved into the peritoneum after surgery (Almadrones, 2007).

Catheters used for IP therapy may be an implanted port for long-term treatment or an external catheter for temporary use. These catheters, including those attached to an implanted port, have large internal lumens with multiple side-holes along the catheter length to allow for delivery of large quantities of fluid. Administration of IP therapy includes three phases: the instillation phase; the dwell phase, usually 1 to 4 hours; and the drain phase. Because this treatment involves the delivery of biohazardous agents, additional competency is required to handle the infusion properly.

The patient should be in the semi-Fowler's position for the infusion. He or she may experience nausea and vomiting caused by increasing pressure on the internal organs from the

infusing fluid. Pressure on the diaphragm may cause respiratory distress. Reducing the flow rate and treatment with anti-emetic drugs may be needed. Severe pain may indicate that the catheter has migrated, and an abdominal x-ray is needed to determine its location.

During the dwell and drainage phases, the patient may need assistance in frequently moving from side to side to distribute the fluid evenly around the abdominal cavity. After the fluid has drained, the catheter is flushed with normal saline, although heparinized saline may be used in implanted ports. Catheter lumen occlusion is caused by the formation of fibrous sheaths or fibrin clots or plugs inside the catheter or around the tip.

Exit site infection, indicated by redness, tenderness, and warmth of the tissue around the catheter, can occur. Microbial peritonitis and inflammation of the peritoneal membranes from the invasion of microorganisms are other complications. If peritonitis occurs, the patient may experience a fever and report abdominal pain. Abdominal rigidity and rebound tenderness may be present. This condition is preventable by using strict aseptic technique in the handling of all equipment and infusion supplies. Management includes antimicrobial therapy administered either IV or intraperitoneally.

Intraspinal Infusion

The spinal column is covered by three layers: the dura mater, or outermost covering; the arachnoid, or middle layer; and the pia mater, which is closest to the spinal cord. Two spaces used for infusion are the **epidural** space between the dura mater and vertebrae and the **subarachnoid** space. The epidural space consists of fat, connective tissue, and blood vessels that protect the spinal cord. Medications infused into the epidural space must diffuse through the dura mater, and there is the possibility that some drug will be absorbed systemically. **Intrathecal** medications are infused into the subarachnoid space closer to the spinal cord, allowing reduced doses.

Description

Postoperative and chronic pain management are the primary indications for epidural infusion. Opioids administered epidurally slowly diffuse across the dura mater to the dorsal horn of the spinal cord. They lock onto receptors and block pain impulses from ascending to the brain. The patient receives pain relief from the level of the injection caudally (toward the toes). Local anesthetics administered epidurally work on the sensory nerve roots in the epidural space to block pain impulses. The physician administers the first dose of medication; then, depending on state law, the type of medication, and facility policies, nurses trained in epidural therapy may administer subsequent doses.

Intrathecal infusion is used for treating cancers that cross the blood-brain barrier and involve the central nervous system (CNS). Some medications used to treat CNS neoplasms, such as methotrexate and cytarabine, are not effective IV because they cannot cross the blood-brain barrier. Others must be administered in large doses to cross this natural protective mechanism. It may not be possible to administer large doses of chemotherapeutic agents IV because of the severe systemic side effects associated with them. Administration of medications via the intrathecal route eliminates this problem because they are administered directly into the

cerebrospinal fluid (CSF). Intrathecal infusion is also used to treat spasticity of neurologic diseases such as cerebral palsy, multiple sclerosis, reflex sympathetic dystrophy, and traumatic and anoxic acquired brain injuries.

A temporary catheter used for epidural therapy can be a percutaneous catheter that is secured at the site and extends up the back toward the shoulder. These catheters are used for postoperative pain management and usually dwell for only several hours or a few days. Infection and subsequent meningitis and catheter migration are the possible complications.

Epidural catheters used for longer periods include a tunneled catheter and implanted port. Tunneled catheters are tunneled toward the abdomen and have a subcutaneous cuff to act as a barrier to infection. The external catheter exits the skin on the abdomen, so it can be easily reached for use by the patient or caregiver. An epidural implanted port is the same design as an IV implanted port and is accessed with the same noncoring needle. The catheter extends from the lumbar puncture site to the port pocket and is located over a bony prominence on the abdomen through a subcutaneous tunnel. Surgically implanted pumps can also be used to deliver epidural and intrathecal infusion.

Nursing Care

Using sterile techniques, intraspinal catheters usually are inserted in the lumbar region. The external portion of a temporary epidural catheter is laid along the back toward the head and usually extends over the shoulder. The entire catheter length is taped for added security. Dressings are usually not routinely changed because they are used only for short periods. If bleeding or fluid leakage requires dressing removal, extreme care is required to prevent dislodging the catheter.

For a tunneled catheter or implanted port, the entire subcutaneous tunnel and port pocket should be frequently assessed. Measurement of an external catheter segment could help identify catheter migration.

An in-line filter is used on all intraspinal infusions to block the infusion of particulate matter. Medications commonly contain preservatives such as alcohol, phenols, or sulfites; however, these are toxic to the CNS. All medications used for intraspinal infusion must be free of preservatives. Alcohol and products containing alcohol should not be applied to the insertion site because the solution could track along the catheter and cause nerve damage. Povidone-iodine solutions are preferred for skin antisepsis before insertion and during catheter dwell, including tunneled catheter exit sites and implanted port pockets.

Complications from epidural and intrathecal infusion can be caused by the type of medication being infused or can be related to the catheter. It is important to know the specific location of the intraspinal catheter because the doses of medications are quite different. When used for pain management, doses are usually 10 times greater for epidural than for intrathecal infusion. Assess the patient for response to the drugs being given, level of alertness, respiratory status, and itching.

Catheter-related complications include infection, bleeding, leakage of CSF, occlusion of the catheter lumen, and catheter migration. Infection in the patient receiving either epidural or intrathecal therapy could be the result of a lack of asepsis when handling the medication or during the administration. Evidence of local infection, such as redness or swelling at the catheter exit site, may be present. The patient may also exhibit neurologic and systemic signs of infection (e.g., meningitis), such as headache, stiff neck, or temperature higher than 101° F (38.3° C). Report any neurologic change to the health care provider immediately!

GET READY FOR THE NCLEX® EXAMINATION!

KEY POINTS

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Check intravenous (IV) administration orders for accuracy and completeness before implementing them.
- Prevent IV administration errors by using smart pumps and other emerging technology-based safety infusion systems.
- Devices engineered with safety mechanisms are required by the Occupational Safety and Health Administration (OSHA) to prevent staff injuries from needles, thus preventing bloodborne pathogen hazards.
- Use the evidence-based catheter-related bloodstream infection (CR-BSI) prevention bundle during insertion and care of central lines.
- Teach patients and their families about the patient's infusion therapy, including purpose, type, and safety precautions.

Health Promotion and Maintenance

- Older adults present special challenges when infusion therapy is used; physiologic changes of the skin and cardiac/renal systems must be considered.
- Use small IV catheters for older adults, and insert using a 10- to 15-degree angle to prevent rolling of the vein.

Physiological Integrity

- Infusion therapy is the delivery of parenteral medications and fluids through a wide variety of catheters and locations.
- Infusion therapy is used for establishing fluid and electrolyte balance, achieving optimum nutrition, maintaining hemostasis, and treating or preventing illnesses with medications.
- Vascular access devices (VADs) are catheters that are used to deliver fluids, electrolytes, and medications into the intravascular space.

GET READY FOR THE NCLEX® EXAMINATION! —cont'd

- Common types of VADs include short peripheral catheters, midline catheters, peripherally inserted central catheters (PICCs), nontunneled percutaneous and tunneled central catheters, implanted ports, and hemodialysis catheters.
- Use best practice for placement of short peripheral VADs, including avoiding the small veins of the hands (see [Chart 15-1](#)).
- Document care for the patient receiving IV therapy, including the type of VAD inserted.
- The type of VAD that is used depends on the reason for infusion therapy, the patient's condition, and the length of therapy.
- Choose the appropriate peripheral catheter gauge size of the VAD depending on its purpose (see [Table 15-1](#)).
- PICCs, tunneled central catheters, and implanted ports are commonly used for long-term infusion therapy.
- Infusion controllers and pumps are electronic devices used to regulate the flow of infusion fluids and medications, but be sure to monitor the infusion rate.
- Nursing care for patients receiving all types of infusion therapy includes using sterile technique when starting the therapy and when changing components of the infusion system, changing and securing the site dressing, and assessing the site for local complications (see [Table 15-2](#)).
- Assess and document the presence of phlebitis using the INS Phlebitis Scale (see [Table 15-6](#)).
- Use normal saline to flush IV catheters on a periodic basis per agency policy.
- Assess, prevent, and manage systemic complications related to IV therapy as outlined in [Table 15-3](#).
- Assess for common complications associated with CVAD insertion as described in [Table 15-4](#).
- Assess, prevent, and manage complications during the course of central IV therapy as listed in [Table 15-5](#).
- Arterial therapy is used primarily for the administration of chemotherapy agents directly into a tumor site; the liver is the most common arterial site for this purpose.
- Intraperitoneal therapy is used for chemotherapy agent administration into the peritoneal cavity, especially for ovarian and gastrointestinal tumors that have metastasized into the peritoneum.
- Subcutaneous therapy of fluids (hypodermoclysis) involves a slow infusion for a short time; the thighs, hips, and abdomen are commonly used.
- Epidural and intrathecal administration of medications are the common uses for intraspinal infusion. Epidural infusions are usually for pain management; intrathecal infusions are usually chemotherapy agents used for cancers that cross the blood-brain barrier into the central nervous system.
- Intraosseous therapy allows fluids and medications to be absorbed by the rich vascular network of the bones; it is used for both children and adults, particularly in emergency situations.

Key Points

Review Questions for the NCLEX® Examination

LEARNING OUTCOMES**Safe and Effective Care Environment**

1. Differentiate among the various types and purposes of surgery.
2. Examine individual patient factors for potential threats to safety, especially for older adults.
3. Use appropriate patient identifiers when providing instruction, administering drugs, marking surgical sites, and performing any procedure.
4. Verify that the patient has given informed consent for the surgical procedure and that the presurgical checklist is complete and accurate.
5. Identify patient conditions or issues that need to be communicated to other members of the surgical and postoperative teams.

Psychosocial Integrity

6. Use effective communication when teaching patients and family members about what to expect during the surgical experience.

7. Act as a patient advocate with regard to patients' rights, informed consent, and advance directives.
8. Identify learning needs for the patient preparing for surgery.

Physiological Integrity

9. Use knowledge of physiology and behavioral principles to describe an accurate and complete preoperative assessment.
10. Evaluate personal factors that increase the patient's risk for complications during and immediately after surgery.
11. Evaluate laboratory values for changes that may affect the patient's response to drugs, anesthesia, and surgery.
12. Explain the purposes and techniques commonly used for patient preoperative preparation.
13. Apply antiembolic stockings, sequential compression boots, or other devices to reduce or prevent vascular complications.

Advances that have provided many benefits to the patient undergoing surgery include those in surgical techniques, anesthesia, pharmacology, medical devices, and supportive interventions. Research defining best practices has resulted in improved outcomes in all areas of the perioperative experience. New diagnostic and intervention devices for the use and refinement of new surgical techniques are continually being developed. Examples of such technical advances now in common use include robotics and many other types of minimally invasive surgeries (MISs). Advances in anesthetic agents and techniques improve the ways that a surgical patient is treated and has made anesthesia safer than ever before. Many procedures that used to be performed only in the operating room are now being done in other departments such as interventional radiology, cardiac catheterization, and endoscopy. These changes affect the role of the perioperative nurse and have an impact on how patient teaching is performed.

Cost-reduction policies are also a driving force for the management of the surgical patient. Shortened stays and ambulatory surgical services are common. Some patients may only be observed after surgery and may not be admitted as an inpatient. In response to the ongoing health care delivery changes and the use of multiple settings, nurses have modified their interventions, remaining focused on patient care before (**preoperative**), during (**intraoperative**), and after (**postoperative**) surgery. Together, these time periods are known as the **perioperative** experience.

Patient safety throughout the perioperative period is the number-one priority for all personnel. Fig. 16-1 shows an overview of the preoperative activities for patient safety recommended by the World Health Organization (WHO), The Joint Commission (TJC), and the Association of periOperative Registered Nurses (AORN).

Because surgery is invasive and involves exposure to various anesthetic agents and drugs, as well as positioning and other environmental hazards, complications are common. Some complications are predictable and are considered preventable. As a result, TJC has partnered with other groups and agencies and developed a plan for the reduction and eventual elimination of preventable surgical complications known as the Surgical Care Improvement Project (SCIP). Implementation of these core measures is now mandatory for patient safety. The current plan focuses on prevention of infection, prevention of serious cardiac events, and prevention of venous thromboembolism (VTE). Ten specific core measures have been identified as actions required for prevention of these complications in patients identified to be at risk. Table 16-1 provides an overview of these core measure areas. (The numbers associated with the core measures are not always chronological, indicating that some areas are still in development.) The preoperative areas of responsibility for these core measures and their prevention strategies are highlighted in the appropriate areas of this chapter. In addition, some core measures are discussed in patient care chapters most associated with the complication.

OVERVIEW

The preoperative period begins when the patient is scheduled for surgery and ends at the time of transfer to the surgical

suite. As a nurse, you will function as an educator, an advocate, and a promoter of health. The surgical environment demands the use of knowledge, judgment, and skills based on the principles of nursing science. Perioperative nursing places special emphasis on safety, advocacy, and patient education, although ensuring a “culture of safety” is the responsibility of all health care team members (Scherer & Fitzpatrick, 2008).

The patient’s readiness for surgery is critical to the outcome. Preoperative care focuses on preparing the patient for the surgery and patient safety. This care includes education and any intervention needed before surgery to reduce anxiety and complications and to promote patient cooperation in procedures after surgery. Use adult teaching and learning principles in teaching patients and families before surgery. Validate, clarify, and reinforce information the patient has received from the surgeon or other members of the surgical team. In addition, during the nursing assessment before surgery, problems may be identified that warrant further patient assessment or intervention before the procedure. As required by The Joint Commission’s National Patient Safety Goals (NPSGs), communication and collaboration with the surgical team are essential so that correct actions are taken to achieve the desired outcome.

Categories and Purposes of Surgery

Surgical procedures are categorized by the purpose, body location, extent, and degree of urgency. Table 16-2 explains the categories and gives examples of surgical procedures.

Surgical Settings

The term **inpatient** refers to a patient who is admitted to a hospital. The patient may be admitted the day before or, more often, the day of surgery (often termed same-day admission [SDA]), or the patient may already be an inpatient when surgery is needed. The terms **outpatient** and **ambulatory** refer to a patient who goes to the surgical area the day of the surgery and returns home on the same day (i.e., *same-day surgery* [SDS]). Hospital-based ambulatory surgical centers, freestanding surgical centers, physicians’ offices, and ambulatory care centers are common. More than half of all surgical procedures in North America are performed in ambulatory centers (CDC, 2008).

One advantage of outpatient surgery is that patients are not separated from the comfort and security of their home and family. With improvements in surgical techniques and anesthesia, more procedures are performed safely on an outpatient basis. Same-day surgery, however, presents new challenges for the patient who does not have an adequate or available support system. An older spouse may be unable to assist in care before or after surgery. Patients who are responsible for others may be unable to perform their usual tasks within the family. They may try to continue their family role but jeopardize their own health by doing so. As a result, their stress, fears, and anxieties about the surgical experience and about returning home immediately after surgery may increase. In these circumstances, a case manager may be assigned to coordinate post-discharge care for the patient.

The JC does not stipulate which team member initiates any section of the checklist except for site marking.

The Joint Commission also does not stipulate where these activities occur. See the Universal Protocol for details on The Joint Commission requirements.

FIG. 16-1 An overview of perioperative activities for patient safety recommended by the World Health Organization (WHO), The Joint Commission (TJC), and the Association of periOperative Registered Nurses (AORN).

TABLE 16-1 SURGICAL CARE IMPROVEMENT PROJECT CORE MEASURE OVERVIEW

CORE MEASURE IDENTIFICATION	MEASUREMENT NAME/DESCRIPTION
SCIP Infection-1 (SCIP Inf-1)	<i>Prophylactic Antibiotic Received Within One Hour Prior to Surgical Incision</i> The purpose is to use short-duration antibiotics to establish bactericidal blood and tissue levels by the time the surgical incision is made.
SCIP Infection-2 (SCIP Inf-2)	<i>Prophylactic Antibiotic Selection for Surgical Patients</i> The purpose is to ensure that prophylactic antibiotics are used for patients who are at increased risk for surgical site infections. The guidelines for risk and for the exact antibiotic to be used are specific to each type of surgical procedure and follow evidence-based published recommendations.
SCIP Infection-3 (SCIP Inf-3)	<i>Prophylactic Antibiotics Discontinued Within 24 Hours After Surgery End Time</i> The purpose is to ensure that prophylactic antibiotic therapy provides benefit without risk. Prolonged prophylactic antibiotic therapy has not been shown to increase benefit and is known to increase the risk for <i>C. difficile</i> infection and the development of microorganisms that are resistant to antimicrobial drugs.
SCIP Infection-4 (SCIP Inf-4)	<i>Cardiac Surgery Patients with Controlled 6 AM Postoperative Blood Glucose</i> (Applies to cardiac surgery patients only) The purpose is to avoid hyperglycemia (which is defined as blood glucose levels above 200 mg/dL and is associated with increased complications and mortality) in cardiac surgery patients, especially patients undergoing coronary artery bypass graft surgery and patients with diabetes who are having cardiac surgery.
SCIP Infection-6 (SCIP Inf-6)	<i>Surgery Patients with Appropriate Hair Removal</i> The purpose is to avoid hair removal procedures, specifically shaving, that cause skin abrasions and increase the risk for surgical site infections. If hair must be removed from the surgical site, removal is performed with electric clippers or chemical depilatories.
SCIP Infection-9 (SCIP Inf-9)	<i>Urinary Catheter Removed on Postoperative Day 1 (POD 1) or Postoperative Day 2 (POD 2) with Day of Surgery Being Day Zero</i> The purpose is to avoid urinary catheter-associated urinary tract infections, which increase with longer duration indwelling catheters. It is unacceptable to have an indwelling urinary catheter in place longer than 48 hours after surgery unless there is a documented specific and medically validated reason for it.
SCIP Infection-10 (SCIP Inf-10)	<i>Surgery Patients with Perioperative Temperature Management</i> The purpose is to prevent prolonged hypothermia, which is associated with impaired wound healing, serious cardiac complications, altered drug metabolism, coagulation problems, and a higher incidence of surgical site infections. Temperature must be measured within 15 minutes from the end of anesthesia administration. Intentional hypothermia must be documented.
SCIP CARD-2	<i>Surgery Patients on Beta-Blocker Therapy Prior to Arrival Who Received a Beta-Blocker During the Perioperative Period</i> The purpose is to ensure that patients with specific medical conditions receive beta-blocker therapy before surgery and continue the therapy in the immediate postoperative period. This evidence-based action has resulted in a significant reduction in coronary events, cardiovascular mortality, and overall mortality.
SCIP Venous thromboembolism-1 (SCIP VTE-1)	<i>Surgery Patients with Recommended Venous Thromboembolism Prophylaxis Ordered</i> The purpose is to reduce the complications from postoperative venous thromboembolism (VTE). Surgery is a major risk factor responsible for VTE formation and subsequent pulmonary embolism. Although VTE prophylaxis is effective, it is underused. Specific preoperative and postoperative VTE prophylaxis strategies are recommended on the basis of patient risk, type and duration of surgery, and extent of expected postoperative immobilization.
SCIP Venous thromboembolism-2 (SCIP VTE-2)	<i>Surgery Patients Who Received Appropriate Venous Thromboembolism Prophylaxis Within 24 Hours Prior to Surgery to 24 Hours After Surgery</i> The purpose is to reduce the complications from postoperative venous thromboembolism (VTE), particularly among patients undergoing the types of surgeries in which the risk is highest.

Information compiled from The Joint Commission. (2010). *National Patient Safety Goals*. Retrieved October 2010 from <http://www.jointcommission.org/patientsafety/nationalpatientsafetygoals/>.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

History

Data collection about the patient before surgery begins in various settings (e.g., the surgeon's office, the preadmission or admission office, the inpatient unit, the telephone). Use privacy to increase the patient's comfort with the interview process. Anesthesia and surgery are both physical and emotional stressors. Collect these data:

- Age
- Use of tobacco, alcohol, or illicit substances, including marijuana
- Current drugs
- Use of complementary or alternative practices, such as herbal therapies, folk remedies, or acupuncture
- Medical history
- Prior surgical procedures and how these were tolerated
- Prior experience with anesthesia, pain control, and management of nausea or vomiting
- Autologous or directed blood donations
- Allergies, including sensitivity to latex products
- General health
- Family history
- Type of surgery planned
- Knowledge about and understanding of events during the perioperative period
- Adequacy of the patient's support system

TABLE 16-2 SELECTED CATEGORIES OF SURGICAL PROCEDURES

CATEGORY	DESCRIPTION	CONDITION OR SURGICAL PROCEDURE	CATEGORY	DESCRIPTION	CONDITION OR SURGICAL PROCEDURE
Reasons for Surgery			Degree of Risk of Surgery		
Diagnostic	Performed to determine the origin and cause of a disorder or the cell type for cancer	Breast biopsy Exploratory laparotomy Arthroscopy	Minor	Procedure without significant risk; often done with local anesthesia	Incision and drainage (I&D) Implantation of a venous access device (VAD) Muscle biopsy
Curative	Performed to resolve a health problem by repairing or removing the cause	Cholecystectomy Appendectomy Hysterectomy	Major	Procedure of greater risk; usually longer and more extensive than a minor procedure	Mitral valve replacement Pancreas transplant Lymph node dissection
Restorative	Performed to improve a patient's functional ability	Total knee replacement Finger reimplantation	Extent of Surgery		
Palliative	Performed to relieve symptoms of a disease process, but does not cure	Colostomy Nerve root resection Tumor debulking Ileostomy	Simple	Only the most overtly affected areas involved in the surgery	Simple/partial mastectomy
Cosmetic	Performed primarily to alter or enhance personal appearance	Liposuction Revision of scars Rhinoplasty Blepharoplasty	Radical	Extensive surgery beyond the area obviously involved; is directed at finding a root cause	Radical prostatectomy Radical hysterectomy
Urgency of Surgery			Minimally invasive surgery (MIS)	Surgery performed in a body cavity or body area through one or more endoscopes; can correct problems, remove organs, take tissue for biopsy, re-route blood vessels and drainage systems; is a fast-growing and ever-changing type of surgery	Arthroscopy Tubal ligation Hysterectomy Lung lobectomy Coronary artery bypass Cholecystectomy
Elective	Planned for correction of a nonacute problem	Cataract removal Hernia repair Hemorrhoidectomy Total joint replacement			
Urgent	Requires prompt intervention; may be life threatening if treatment is delayed more than 24 to 48 hr	Intestinal obstruction Bladder obstruction Kidney or ureteral stones Bone fracture Eye injury Acute cholecystitis			
Emergent	Requires immediate intervention because of life-threatening consequences	Gunshot or stab wound Severe bleeding Abdominal aortic aneurysm Compound fracture Appendectomy			

When taking a history, screen the patient for problems that increase the risk for complications during and after surgery. Some problems that increase the surgical risk or increase the risk for complications after surgery are listed in [Table 16-3](#).

Older patients are at increased risk for complications ([Doerflinger, 2009](#)). The normal aging process decreases immune system functioning and delays wound healing. The frequency of chronic illness increases in older patients. In addition, reductions of muscle mass and body water increase the risk for dehydration. See [Chart 16-1](#) for other changes in older adults that may alter the operative response or risk.

Drugs and substance use may affect patient responses to surgery. The use of tobacco increases the risk for pulmonary complications because of changes it causes to the lungs and chest cavity. Excessive alcohol and illicit substance use can alter the patient's responses to anesthesia and pain medication. Withdrawal of alcohol before surgery may lead to delirium tremens. Prescription and over-the-counter drugs may also affect how the patient reacts to the operative experience.

Adverse effects can occur with the use of some herbs, such as those listed in [Table 16-4](#).

Medical history is important to obtain because many chronic illnesses increase surgical risks and need to be considered when planning care ([Woolger, 2008](#)). For example, a patient with systemic lupus erythematosus may need additional drugs to offset the stress of the surgery. A patient with diabetes may need a more extensive bowel preparation because of decreased intestinal motility. An infection may need to be treated before surgery.

Ask the patient specifically about cardiac disease because complications from anesthesia occur more often in patients with cardiac problems ([Morse, 2009](#); [Johnson, 2011](#)). A patient with a history of rheumatic heart disease may be prescribed antibiotics before surgery. Cardiac problems that increase surgical risks include coronary artery disease, angina, myocardial infarction (MI) within 6 months before surgery, heart failure, hypertension, and dysrhythmias. These problems impair the patient's ability to withstand hemodynamic changes and alter the response to anesthesia. The risk for an

TABLE 16-3 SELECTED FACTORS THAT INCREASE SURGICAL RISK OR INCREASE THE RISK FOR POSTOPERATIVE COMPLICATIONS

Age

- Older than 65 years

Medications

- Antihypertensives
- Tricyclic antidepressants
- Anticoagulants
- Nonsteroidal anti-inflammatory drugs (NSAIDs)

Medical History

- Decreased immunity
- Diabetes
- Pulmonary disease
- Cardiac disease
- Hemodynamic instability
- Multisystem disease
- Coagulation defect or disorder
- Anemia
- Dehydration
- Infection
- Hypertension
- Hypotension
- Any chronic disease

Prior Surgical Experiences

- Less-than-optimal emotional reaction
- Anesthesia reactions or complications
- Postoperative complications

Health History

- Malnutrition or obesity
- Drug, tobacco, alcohol, or illicit substance use or abuse
- Altered coping ability

Family History

- Malignant hyperthermia
- Cancer
- Bleeding disorder

Type of Surgical Procedure Planned

- Neck, oral, or facial procedures (airway complications)
- Chest or high abdominal procedures (pulmonary complications)
- Abdominal surgery (paralytic ileus, venous thromboembolism)

MI during surgery is higher in patients who have heart problems. Patients with cardiac disease may require perioperative therapy with beta-blocking drugs, as recommended by core measures for SCIP CARD-2 (see [Table 16-1](#)).

Pulmonary complications during or after surgery are more likely to occur in older patients, those with chronic respiratory problems, and smokers because of smoking- or age-related lung changes ([Doerflinger, 2009](#)). Increased chest rigidity and loss of lung elasticity reduce anesthetic excretion. Smoking increases the blood level of **carboxyhemoglobin** (carbon monoxide on oxygen-binding sites of the hemoglobin molecule), which decreases oxygen delivery to organs. Action of cilia in pulmonary mucous membranes decreases, which leads to retained secretions and predisposes the patient to infection (pneumonia) and **atelectasis** (collapse of alveoli). Atelectasis reduces gas exchange and causes intolerance of anesthesia. It is also a common problem after general anesthesia.

Chronic lung problems such as asthma, emphysema, and chronic bronchitis also reduce the elasticity of the lungs,

TABLE 16-4 POTENTIAL EFFECTS OF HERBS

HERB	POTENTIAL EFFECT
Black cohosh	Bradycardia, hypotension, joint pains
Bloodroot	Bradycardia, dysrhythmia, dizziness, impaired vision, intense thirst
Boneset	Liver toxicity, mental changes, respiratory problems
Coltsfoot	Fever, liver toxicity
Dandelion	Interactions with diuretics, increased concentration of lithium or potassium
Ephedra	Headache, dizziness, insomnia, tachycardia, hypertension, anxiety, irritability, dry mouth
Feverfew	Interference with blood-clotting mechanisms
Garlic	Hypotension, blood-clotting inhibition, potentiation of diabetes drugs
Ginseng	Headache, anxiety, insomnia, hypertension, tachycardia, asthma attacks, postmenopausal bleeding
Goldenseal	Vasoconstriction
Hawthorn	Hypotension
Kava	Damage to the eyes, skin, liver, and spinal cord from long-term use
Licorice	Hyperkalemia, hyponatremia
Lobelia	Hearing and vision problems
Motherwort	Increased anticoagulation
Nettle	Hypokalemia
Senna	Potentiation of digoxin
St. John's wort	Antidepressant, photosensitivity
Valerian root	Mild sedative or tranquilizer effect, hepatotoxicity

which reduces gas exchange. As a result, patients with these problems have reduced tissue oxygenation.

Previous surgical procedures and anesthesia affect the patient's readiness for surgery. Previous experiences, especially with complications, may increase anxiety about the scheduled surgery. Ask about the patient's experience with anesthesia and all allergies. These data provide information about tolerance of and possible fears about the use of anesthesia. The family medical history and problems with anesthetics may indicate possible reactions to anesthesia, such as malignant hyperthermia (see [Chapter 17](#)).

A sensitivity or allergy to certain substances alerts you to a possible reaction to anesthetic agents or to substances that are used before or during surgery. For example, povidone-iodine (e.g., Betadine) used for skin cleansing contains the same allergens found in shellfish. Patients who are allergic to shellfish may have an adverse reaction to povidone-iodine. The patient with an allergy to bananas and other fruits may also have a latex sensitivity or allergy.

Blood donation for surgery can be made by the patient (**autologous donations**) a few weeks just before the scheduled surgery date. Then, if blood is needed during or after surgery, an autologous blood transfusion can be given. This practice eliminates transfusion reactions and reduces the risk for acquiring bloodborne disease.

Patients can donate their own blood up to 5 weeks before surgery if they are infection free, have a hemoglobin level greater than 11 g/dL (110 g/L), and have a physician's

CHART 16-1 NURSING FOCUS ON THE OLDER ADULT

Changes of Aging as Surgical Risk Factors

PHYSIOLOGIC CHANGE	NURSING INTERVENTIONS	RATIONALES
Cardiovascular System Decreased cardiac output Increased blood pressure Decreased peripheral circulation	Determine normal activity levels, and note when the patient tires. Monitor vital signs, peripheral pulses, and capillary refill.	Knowing limits helps prevent fatigue. Having baseline data helps detect deviations.
Respiratory System Reduced vital capacity Loss of lung elasticity Decreased oxygenation of blood	Teach coughing and deep-breathing exercises. Monitor respirations and breathing effort.	Pulmonary exercises help prevent pulmonary complications. Having baseline data helps detect deviations.
Renal/Urinary System Decreased blood flow to kidneys Reduced ability to excrete waste Decline in glomerular filtration rate Nocturia common	Monitor intake and output. Assess overall hydration. Monitor electrolyte status. Assist frequently with toileting needs, especially at night.	Ongoing assessment helps detect fluid and electrolyte imbalances and decreased renal function. Frequent toileting helps prevent incontinence and falls.
Neurologic System Sensory deficits Slower reaction time Decreased ability to adjust to changes in the surroundings	Orient the patient to the surroundings. Allow extra time for teaching the patient. Provide for the patient's safety.	An individualized preoperative teaching plan is developed based on the patient's orientation and any neurologic deficits. Safety measures help prevent falls and injury.
Musculoskeletal System Increased incidence of deformities related to osteoporosis or arthritis	Assess the patient's mobility. Teach turning and positioning. Encourage ambulation. Place on falls precautions, if indicated.	Interventions help prevent complications of immobility. Safety measures help prevent injury.
Skin Dry with less subcutaneous fat makes the skin at greater risk for damage; slower skin healing increases risk for infection	Assess the patient's skin before surgery for lesions, bruises, and areas of decreased circulation. Pad bony prominences. Use pressure-avoiding or pressure-reducing overlays. Avoid applying tape to skin. Teach the patient to change position at least every 2 hours.	Having baseline data helps detect changes and evaluate interventions. Padding can protect at-risk areas. Overlays can prevent pressure ulcer formation by redistributing body weight. Tape removal damages thin skin. Changing position frequently helps prevent reduced blood flow to an area and changes external pressure patterns.

prescription. Patients with cardiac disease may need additional clearance from their cardiologist before making an autologous donation. The physician may prescribe supplemental iron before the first donation. Autologous donations can be made as often as every 3 days if other criteria are met. Usually a total of 2 to 4 units are donated. The last donation cannot be made within 72 hours before surgery.

A special tag is placed on the blood bag when an autologous blood donation has been made. The blood donor center gives the patient a matching tag that he or she wears or brings to the surgical area before surgery, as required by The Joint Commission's National Patient Safety Goals (NPSGs). This procedure helps ensure that patients receive only their own blood. If the blood is not used, some agencies discard it. In other agencies, the blood goes to the blood bank where it is processed into various blood components (e.g., plasma, packed cells, platelets) for infusion in other patients.

Patients may wish to have family and friends donate blood exclusively for their use, if needed. This practice (called *directed blood donation*) is possible only if the blood types are compatible and the donor's blood is acceptable. Patients

may fear disease transmission from unknown blood and feel more comfortable knowing who gave the blood. Many centers do not accept directed blood, stating that it gives a false sense of security. As with autologous blood donations, a special tag is attached to the blood bag. This tag notes the names of the patient and the donor and bears the patient's signature.

Ask whether autologous or directed blood donations have been made, and document this information in the chart. It is important to know the specific blood collection center where the donation was made and whether the blood has arrived before the patient goes into surgery. The hospital receives and stores the blood units until they are used or are no longer needed. Unused blood is returned to the collection center.

Increased use of "bloodless surgery" and minimally invasive surgery provides alternatives for patients with religious or medical restrictions to blood transfusions. These programs reduce the need for transfusion during and after surgery. Some techniques used are limiting blood samples (the number of samples, as well as the volume of blood drawn per sample) before surgery and stimulating the patient's own red

blood cell production with epoetin alpha (e.g., Epogen, Procrit) before, during, and after surgery. Supplemental iron, folic acid, vitamin B₁₂, and vitamin C may be prescribed before surgery to help red blood cell formation. Newer equipment and surgical techniques cause less blood loss than older techniques. Such advances include recycling blood suctioned during surgery and immediately transfusing it back into the patient. Assess, monitor, teach, and support the patient during the bloodless surgery process.

Discharge planning is started before surgery. Assess the patient's home environment, self-care capabilities, and support systems and anticipate postoperative needs before surgery. *All patients, regardless of how minor the procedure or how often they have had surgery, should have discharge planning.* Older patients and dependent adults may need transportation referrals to and from the physician's office or the surgical setting. A home care nurse may be needed to monitor recovery and to provide instructions. All patients with few support systems may need follow-up care at home. Some patients need a planned direct admission to a rehabilitation hospital or center for physical therapy after surgery, especially joint replacement surgery (Lucas, 2008). Shortened hospital stays require adequate discharge planning to achieve the desired outcomes after surgery.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

On admission to the preoperative area, the client scheduled for a hip replacement tells the nurse that three autologous blood donations for this surgery have been made in the past 3 weeks. What is the nurse's best action?

- Check the client's international normalized ratio (INR).
- Call the laboratory to ensure that the blood is physically at the operating facility.
- Ensure that the client has given consent to receive blood if a transfusion is necessary.
- Inform the client that an autologous transfusion does not eliminate the risk for development of bloodborne diseases.

Physical Assessment/Clinical Manifestations

The preoperative patient may be any age, with a health status that varies from well to debilitated. Perform a complete assessment before surgery to obtain baseline data. During assessment, identify current health problems, potential complications related to anesthesia, and possible complications that may occur after surgery.

When beginning the assessment, obtain a complete set of vital signs. You may need to obtain vital signs several times at different time intervals for accurate baseline values. Previous vital signs from another admission (if available) are helpful to compare with current vital signs. Abnormal vital signs may require postponement of surgery until the problem is treated and the patient's condition is stable. Also assess for anxiety, which could increase blood pressure, pulse, and respiratory rate. Document these findings as part of the overall assessment.

Throughout the physical assessment, focus on problem areas identified from the patient's history and on all body systems affected by the surgical procedure. The older adult (Chart 16-2; see also Chapter 3) or chronically ill patient is at increased risk for complications during and after surgery. The number of serious problems (**morbidity**) and death

CHART 16-2 NURSING FOCUS ON THE OLDER ADULT

Specific Considerations When Planning Care for the Older Preoperative Patient

- Greater incidence of chronic illness
- Greater incidence of malnutrition
- More allergies
- Increased incidence of impaired self-care abilities
- Inadequate support systems
- Decreased ability to withstand the stress of surgery and anesthesia
- Increased risk for cardiopulmonary complications after surgery
- Risk for a change in mental status when admitted (e.g., related to unfamiliar surroundings, change in routine, drugs)
- Increased risk for a fall and resultant injury

(**mortality**) during or after surgery is higher in older and chronically ill patients (Morse, 2009).

Report any abnormal assessment findings to the surgeon and to anesthesia personnel, as required by The Joint Commission's NPSGs. In this way, you are a proactive patient advocate exercising professional legal responsibility. Often, established protocols or care maps identify what interventions are to be performed before surgery.

Cardiovascular status is critical to assess because cardiac problems may cause as many as 30% of surgery-related deaths. Check the patient for hypertension, which is common, is often undiagnosed, and can affect the response to surgery. Cardiac assessment includes listening to heart sounds for rate, regularity, and abnormalities. Ask whether the patient has ever had a venous thromboembolism (VTE). Examine the patient's hands and feet for temperature, color, peripheral pulses, capillary refill, and edema. Report any problems (e.g., absent peripheral pulses, pitting edema, cardiac symptoms, chest pain, shortness of breath, and dyspnea) to the physician for further assessment and evaluation. (Cardiac assessment is discussed further in Chapter 35.)

Respiratory status considers age, smoking history (including exposure to secondhand smoke), and any chronic illness (Doerflinger, 2009). Observe the patient's posture; respiratory rate, rhythm, and depth; overall respiratory effort; and lung expansion. Document any clubbing of the fingertips (swelling at the base of the nail beds caused by a chronic lack of oxygen) or cyanosis. Auscultate the lungs to assess for any abnormal breath sounds (crackles, wheezes, rubs). (More information on respiratory assessment is found in Chapter 29.)

Kidney function affects the excretion of drugs and waste products, including anesthetic and analgesic agents. If kidney function is reduced, fluid and electrolyte balance can be altered, especially in older patients. Ask about problems such as urinary frequency, **dysuria** (painful urination), **nocturia** (awakening during nighttime sleep because of a need to void), difficulty starting urine flow, and **oliguria** (scant amount of urine). Ask the patient about the appearance and odor of the urine. Equally important is an assessment of usual fluid intake and degree of continence. If the patient has kidney or urinary problems, consult with the physician about further workup. (Kidney/urinary assessment is discussed further in Chapter 68.)

Kidney impairment decreases the excretion of drugs and anesthetic agents. As a result, drug effectiveness may be altered. Scopolamine (Buscopan ) , morphine, other opioids, and barbiturates often cause confusion, disorientation, apprehension, and restlessness when given to patients with decreased kidney function.

Neurologic status includes the patient's overall mental status, level of consciousness, orientation, and ability to follow commands. This information is needed before planning preoperative teaching and care after surgery. A problem in any of these areas affects the type of care needed during the surgical experience. Determine the patient's baseline neurologic status to be able to identify changes that may occur later. Also assess for any motor or sensory deficits. (See [Chapter 43](#) for complete nervous system assessment.)

The usual neurologic status of a mentally impaired patient may be difficult to assess (Doerflinger, 2009; Grebe, 2007). The patient who has been independent and oriented at home may become disoriented in the hospital setting. Family members can often provide information about what the patient was like at home.

The Joint Commission's NPSGs require that you ensure patient safety by assessing the patient's risk for falling, especially older patients. Evaluate factors such as mental status, muscle strength, steadiness of gait, and sense of independence to determine the patient's risk. Document the patient's ability to ambulate and the steadiness of gait as baseline data.

Musculoskeletal status problems may interfere with positioning during and after surgery. For example, patients with arthritis may be able to assume surgical positions but have discomfort after surgery from prolonged joint immobilization. Other anatomic features, such as the shape and length of the neck and the shape of the chest cavity, may interfere with respiratory and cardiac function or require special positioning during surgery.

Ask about a history of joint replacement, and document the exact location of any prostheses. *During surgery, ensure that electrocautery pads, which could cause an electrical burn, are not placed on or near the area of the prosthesis.*

Nutritional status, especially malnutrition and obesity, can increase surgical risk (Woolger, 2008). Surgery increases metabolic rate and depletes potassium, vitamin C, and B vitamins, all of which are needed for wound healing and blood clotting. In malnourished patients, decreased serum protein levels slow recovery. Negative nitrogen balance may result from depleted protein stores. This problem increases the risk for skin breakdown, delayed wound healing, possible dehiscence or evisceration (see [Chapter 18](#)), dehydration, and sepsis.

Some older patients may have poor nutrition because of chronic illness, diuretic or laxative use, poor dietary planning or habits, anorexia, and lack of motivation or financial limitations (Touhy & Jett, 2010). Indications of poor fluid or nutritional status include:

- Brittle nails
- Muscle wasting
- Dry or flaky skin, decreased skin turgor, and hair changes (e.g., dull, sparse, dry)
- Orthostatic (postural) hypotension
- Decreased serum protein levels and abnormal serum electrolyte values

The obese patient is often malnourished because of an imbalanced diet. Obesity increases the risk for poor wound healing

because of excessive **adipose** (fatty) tissue. Fatty tissue has few blood vessels, little collagen, and decreased nutrients, all of which are needed for wound healing. Obesity stresses the heart and reduces the lung volumes, which can affect the surgery and recovery. In addition, obese patients may need larger doses of drugs and may retain them longer after surgery.

Skin assessment is important. Many insurers have denied coverage to hospitals for care provided to patients who develop skin breakdown or pressure ulcers during the perioperative period. Assess the patient's skin for signs of breakdown, open sores, or areas that may receive excessive pressure during the surgical procedure, and document these findings. Communicate this information to the circulating nurse so precautions can be taken to prevent injury.

NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

The client scheduled for knee replacement surgery today performed all of the following actions yesterday. Which action is most important for the nurse to report to the surgeon?

- A. Took 50 mg of diphenhydramine (Benadryl) at bedtime
- B. Smoked one pack of cigarettes instead of two
- C. Drank two 12-ounce glasses of beer
- D. Took two aspirins three times

Psychosocial Assessment

Perform a psychosocial assessment to determine the patient's level of anxiety, coping ability, and support systems. Provide information and offer support as needed.

Most patients have some degree of anxiety before surgery; others may be fearful. The extent of these reactions varies according to the type of surgery, the perceived effects of the surgery and its potential outcome, and the patient's personality. Surgery may be seen as a threat to life, body image, self-esteem, self-concept, or lifestyle. Patients may fear death, pain, helplessness, a change in role or work status, a diagnosis of life-threatening conditions, possible disabling or crippling effects, or the unknown.

Anxiety or fear affects the patient's ability to learn, cope, and cooperate with teaching and operative procedures. Anxiety may also influence the amount and type of anesthetic needed and may slow recovery. In addition, severe preoperative anxiety appears to increase the degree of pain some patients have after surgery. Be aware of potential anxiety when interviewing the patient and planning teaching.

Assess coping mechanisms used by the patient under similar situations or in the past when confronted with a stressful situation. Ask open-ended questions about the patient's feelings about the entire surgical experience. Factors that influence coping include age; previous surgical or sick-role experiences; and emotional and physical signs of fear, anxiety, or discomfort. Signs of anxiety include anger, crying, restlessness, profuse sweating, increased pulse rate, palpitations, sleeplessness, diarrhea, and urinary frequency.

Laboratory Assessment

Laboratory tests before surgery provide baseline data about the patient's health and help predict potential complications (Woolger, 2008). The patient scheduled for surgery in an ambulatory surgical center or admitted to the hospital on the morning of or day before surgery may have preadmission

testing (PAT) performed from 24 hours to 28 days before the scheduled surgery. These test results are usually valid unless there has been a change in the patient's condition that warrants repeated testing or the patient is taking drugs that can alter laboratory values (e.g., warfarin [Coumadin], aspirin, diuretics). Some facilities have time limits for tests, especially pregnancy testing or any other test results that would require altering the surgical plan.

The choice of laboratory testing before surgery varies among facilities and depends on the patient's age, medical history, and type of anesthesia planned (Rothrock & McEwen, 2007). The most common tests include:

- Urinalysis
- Blood type and screen
- Complete blood count or hemoglobin level and hematocrit
- Clotting studies (prothrombin time [PT], international normalized ratio [INR], activated partial thromboplastin time [aPTT], platelet count)
- Electrolyte levels
- Serum creatinine and blood urea nitrogen levels
- Depending on a female patient's age and the nature of the planned procedure, a pregnancy test may also be needed

Urinalysis is performed to assess for abnormal substances in the urine such as protein, glucose, blood, and bacteria. If kidney disease is suspected or if the patient is older, the physician may request other tests to determine the type and degree of disease present.

Report electrolyte imbalances or other abnormal results to the anesthesia team and the surgeon before surgery. **Hypokalemia** (decreased serum potassium level) increases the risk for toxicity if the patient is taking digoxin, slows recovery from anesthesia, and increases cardiac irritability. **Hyperkalemia** (increased serum potassium level) increases the risk for dysrhythmias, especially with the use of anesthesia.

! NURSING SAFETY PRIORITY

Critical Rescue

Any potassium imbalance—hypokalemia or hyperkalemia—must be corrected before surgery.

Other studies may be needed, depending on the patient's medical history. For example, baseline arterial blood gas (ABG) values are assessed before surgery for patients with chronic pulmonary problems. [Chart 16-3](#) lists abnormal laboratory findings and their possible causes.

Imaging Assessment

A chest x-ray may be requested before surgery. Often, young healthy adults are not required to have a chest x-ray. A chest x-ray determines the size and shape of the heart, lungs, and major vessels and provides evidence of the presence of pneumonia or tuberculosis. It also provides baseline data in case of complications. Abnormal x-ray findings alert the surgeon to potential cardiac or pulmonary complications. Heart failure, cardiomyopathy, pneumonia, or infiltrates may cause cancellation or delay of elective surgery. For emergency surgery, x-ray results assist the anesthesia provider in selecting anesthesia.

Other imaging studies are based on patient need, medical history, and the nature of the surgical procedure. For example,

a patient with back pain may have CT scans or MRI examinations before spinal surgery to identify the exact location of the problem.

Other Diagnostic Assessment

An electrocardiogram (ECG) may be required for all patients older than a specific age who are to have general anesthesia. The age varies among facilities but is often 40 to 45 years. An ECG may also be required for patients with a history of cardiac disease or those at risk for cardiac complications. It provides baseline information on new or existing cardiac problems, such as an old myocardial infarction (MI). A patient with a known cardiac problem may need a cardiology consultation before surgery. Drugs for problem prevention, such as nitroglycerin and antibiotics, may be needed throughout the surgical period to reduce or prevent stress on the heart. Abnormal or potentially life-threatening ECG results may cause the cancellation of surgery until the patient's cardiac status is stable.

A focused assessment of the preoperative patient is shown in [Chart 16-4](#).

NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

For which client preadmission testing laboratory result does the nurse take immediate action?

- International normalized ratio 0.9
- White blood cell count 8500/mm³
- Serum potassium level 2.8 mEq/L
- Serum sodium level 132 mEq/L

ANALYSIS

Priority problems for preoperative patients are:

- Insufficient information about the surgical experience related to unfamiliarity with surgical procedures and preparation
- Anxiety related to new or unknown experience, possibility of pain, and possible surgical outcomes

PLANNING AND IMPLEMENTATION

As the nurse, your role is to ensure coordination of care for the patient before surgery. This responsibility continues until the patient is transferred to the OR.

Providing Information

Planning: Expected Outcomes. The patient needs to know what to expect during and after surgery and participate in his or her recovery as indicated by consistently demonstrating these behaviors:

- Explaining in his or her own words the purpose and expected results of the planned surgery
- Asking questions when a term or procedure is not known
- Adhering to the NPO requirements
- Stating an understanding of preoperative preparations (e.g., skin preparation, bowel preparation)
- Demonstrating correct use of exercises and techniques to be used after surgery for the prevention of complications (e.g., splinting the incision, coughing/deep breathing, performing leg exercises, ambulating as early as permitted)

CHART 16-3 LABORATORY PROFILE

Perioperative Assessment

TEST	NORMAL RANGE FOR ADULTS	SIGNIFICANCE OF ABNORMAL FINDINGS	
		INCREASED IN	DECREASED IN
Potassium (K ⁺)	3.5-5.0 mEq/L, or 3.5-5.0 mmol/L	Dehydration Renal failure Acidosis Cellular/tissue damage Hemolysis of the specimen	NPO status when potassium replacement is inadequate Excessive use of non-potassium-sparing diuretics Vomiting Malnutrition Diarrhea Alkalosis
Sodium (Na ⁺)	90 yr or younger: 136-145 mEq/L, or 136-145 mmol/L Older than 90 yr: 132-146 mEq/L, or 132-146 mmol/L	Cardiac or renal failure Hypertension Excessive amounts of IV fluids containing normal saline Edema Dehydration (hemoconcentration)	Nasogastric drainage Vomiting or diarrhea Excessive use of laxatives or diuretics Excessive amounts of IV fluids containing water Syndrome of inappropriate antidiuretic hormone (SIADH)
Chloride (Cl ⁻)	90 yr or younger: 98-106 mEq/L, or 98-106 mmol/L Older than 90 yr: 98-111 mEq/L, or 98-111 mmol/L	Respiratory alkalosis Dehydration Renal failure Excessive amounts of IV fluids containing sodium chloride (NaCl)	Excessive nasogastric drainage Vomiting Excessive use of diuretics Diarrhea
Carbon dioxide (CO ₂)	60 yr or younger: 23-30 mEq/L, or 23-30 mmol/L 60-90 yr: 23-31 mEq/L, or 23-31 mmol/L Older than 90 yr: 20-29 mEq/L, or 20-29 mmol/L	Chronic pulmonary disease Intestinal obstruction Vomiting or nasogastric suctioning Metabolic alkalosis	Hyperventilation Diabetic ketoacidosis Diarrhea Lactic acidosis Renal failure Salicylate toxicity
Glucose (fasting)	60 yr or younger: 70-110 mg/dL, or 4.1-5.9 mmol/L 60-90 yr: 82-115 mg/dL, or 4.6-6.4 mmol/L Older than 90 yr: 75-121 mg/dL, or 4.2-6.7 mmol/L	Hyperglycemia Excessive amounts of IV fluids containing glucose Stress Steroid use Pancreatic or hepatic disease	Hypoglycemia Excess insulin
Creatinine	<i>Females:</i> 60 yr or younger: 0.5-1.1 mg/dL, or 44-97 μmol/L 60-90 yr: 0.6-1.2 mg/dL, or 53-106 μmol/L Older than 90 yr: 0.6-1.3 mg/dL, or 53-115 μmol/L <i>Males:</i> 60 yr or younger: 0.6-1.2 mg/dL, or 53-106 μmol/L 60-90 yr: 0.8-1.3 mg/dL, or 71-115 μmol/L Older than 90 yr: 1.0-1.7 mg/dL, or 88-150 μmol/L	Renal damage with destruction of large number of nephrons Renal insufficiency Acute renal failure Chronic kidney disease End-stage kidney disease (ESKD)	Atrophy of muscle tissue
Blood urea nitrogen (BUN)	Younger than 60 yr: 10-20 mg/dL, or 2.1-7.1 mmol/L 60-90 yr: 8-23 mg/dL, or 2.9-8.2 mmol/L Older than 90 yr: 10-31 mg/dL, or 3.6-11.1 mmol/L	Dehydration Renal failure Excessive protein in diet Liver failure	Overhydration Malnutrition
Prothrombin time (pro time, PT)	11-12.5 sec, 85%-100%, or 1:1.1 patient-control ratio	Coagulation defect (bleeding disorder) Vitamin K deficiency	Coagulation (clotting) disorder, such as thrombophlebitis or pulmonary embolus
International normalized ratio (INR)	0.7-1.8	Anticoagulant therapy (aspirin, warfarin)	Extensive cancer
Partial thromboplastin time, activated (aPTT)	30-40 sec	Coagulation defect (bleeding disorder) Anticoagulant therapy (heparin) Liver disease	Coagulation (clotting) disorder, such as thrombophlebitis or pulmonary embolus Extensive cancer
White blood cell (WBC) count (leukocyte count)	Total: 5,000-10,000/mm ³	Infection Inflammation Stress Tissue necrosis	Immune disorder Immunosuppressant therapy

CHART 16-4 FOCUSED ASSESSMENT

The Preoperative Patient

As part of the cardiopulmonary assessment, take and record vital signs; report:

- Hypotension or hypertension
- Heart rate less than 60 or more than 120 beats/min
- Irregular heart rate
- Chest pain
- Shortness of breath or dyspnea
- Tachypnea
- Pulse oximetry reading of less than 94%

Assess for and report any signs or symptoms of infection, including:

- Fever
- Purulent sputum
- Dysuria or cloudy, foul-smelling urine
- Any red, swollen, draining IV or wound site
- Increased white blood cell count

Assess for and report signs or symptoms that could contraindicate surgery, including:

- Increased prothrombin time (PT), international normalized ratio (INR), or activated partial thromboplastin time (aPTT)
- Hypokalemia or hyperkalemia
- Patient report of possible pregnancy or positive pregnancy test

Assess for and report other clinical conditions that may need to be evaluated by a physician or advanced practice nurse before proceeding with the surgical plans, including:

- Change in mental status
- Vomiting
- Rash
- Recent administration of an anticoagulant drug

Interventions. Because the surgical experience is foreign to many people, focus on teaching the patient and family members (Kruzik, 2009). Teaching may begin in the surgeon's office for planned or elective surgery. Pamphlets, written instructions, and videotapes or DVDs may be given or sent to the patient. More teaching may occur when the patient has preadmission testing. Some facilities hold classes before surgery for groups of patients or show videos for those who are having the same or similar surgical procedures. A tour of the operating suite and the postanesthesia care unit (PACU) may be included.

Explore the patient's level of knowledge and understanding. Increased access to information via the Internet may be helpful but is also a concern. Some Internet information may not be accurate or may not apply to a specific patient's plan of care.

The Joint Commission's NPSGs require that you provide information about informed consent, dietary restrictions, specific preparation for surgery (bowel and skin preparations), exercises after surgery, and plans for pain management to promote patients' participation and help achieve the expected outcome. A sample educational checklist is shown in Table 16-5. Because education occurs in a variety of settings, coordination of patient teaching efforts is challenging. When you care for the patient just before surgery (same-day, ambulatory surgery [outpatient] unit, inpatient hospital unit), assess the patient's and family members' knowledge and provide additional information as needed. Document in the patient record information about who was involved in teaching, what specifically was taught, and what education materials were given to the patient and family.

Ensuring Informed Consent. Surgery of any type involves invasion of the body and requires informed consent from the patient or legal guardian (Fig. 16-2). The Joint Commission's NPSGs state that patients deserve to be informed and involved in decisions affecting their health care. Consent implies that the patient has sufficient information to understand:

- The nature of and reason for surgery
- Who will be performing the surgery and whether others will be present during the procedure (e.g., students)
- All available options and the risks associated with each option
- The risks associated with the surgical procedure and its potential outcomes
- The risks associated with the use of anesthesia

Informed consent is one way to help ensure patient safety. It helps protect the patient from any unwanted procedures and protects the surgeon and the facility from lawsuit claims related to unauthorized surgery or uninformed patients. Written record of informed consent is documented on a "consent form" but can also be documented in the surgeon's notes. The consent form documents the patient's consent and signature for the procedure listed.

TABLE 16-5 PREOPERATIVE TEACHING CHECKLIST

Consider these items when planning individualized preoperative teaching for patients and families:

- Fears and anxieties
- Surgical procedure
- Preoperative routines (e.g., NPO, blood samples, showering)
- Invasive procedures (e.g., lines, catheters)
- Coughing, turning, deep breathing
- Incentive spirometer
 - How to use
 - How to tell when used correctly
- Lower extremity exercises
- Stockings and pneumatic compression devices
- Early ambulation
- Splinting
- Pain management

As a competent adult, it is the patient's right to refuse treatment for any reason, even when refusal might lead to death. For example, in the case of Jehovah's Witnesses, some patients will not accept blood transfusions because of their religious convictions.

The surgeon is responsible for having the consent form signed before sedation is given and before surgery is performed. *You, as a nurse, are not responsible for providing detailed information about the surgical procedure. Rather, your role is to clarify facts that have been presented by the physician and dispel myths that the patient or family may have about the surgical experience. You verify that the consent form is signed, and you serve as a witness to the signature, not to the fact that the patient is informed.*

! NURSING SAFETY PRIORITY

Action Alert

If you believe that the patient has not been adequately informed, contact the surgeon and request that he or she see the patient for further clarification. Document this action in the medical record.

Patients who cannot write may sign with an X, which must be witnessed by two persons. In an emergency, telephone or telegram authorization is acceptable and should be followed up with written consent as soon as possible. The number of witnesses (usually two) and the type of documentation vary according to the facility's policy. In a life-threatening situation in which every effort has been made to contact the person with medical power of attorney, consent is desired but not essential. In place of written or oral consent, written consultation by at least two physicians who are not associated with the case may be requested by the physician. This formal consultation legally supports the decision for surgery until the appropriate person can sign a consent form. If the patient is not capable of giving consent and has no family, the court can appoint a legal guardian to represent the patient's best interests (Grebe, 2007).

A blind patient may sign his or her own consent form, which usually needs to be witnessed by two persons. Patients who have English as a second language (ESL), who do not speak the general language of the facility, or who are hearing impaired may require a qualified translator and a second witness. Many facilities have consent forms written in more than one language and also have health care professionals

who are proficient with American Sign Language. Qualified translators may be health care professionals, other types of hospital employee, or family members (Smith, 2007). They are required to keep patient information confidential.

Some surgical procedures, such as intraocular lens implants, sterilization, and experimental procedures, may require a special permit in addition to the standard consent. National and local governing bodies and the individual facility determine which procedures require a separate permit. Separate consents for anesthesia and blood products may be required.

Surgical procedures that are site-specific, such as left, right, or bilateral, require patient identification before surgery. As required by The Joint Commission's NPSGs, to ensure the correct site is selected and the wrong site is avoided, the site is marked by a licensed independent practitioner and, whenever possible, involves the patient. The practitioner is accountable and should be present during the procedure. The nurse is an important part of this safety measure. Before starting the operative procedure, facilities use a "time-out" procedure to verify the correct site. The perioperative nurse is in a position of ensuring these safety measures are again implemented immediately before the procedure is started (Association of periOperative Registered Nurses [AORN], 2010a; Beyea, 2007; Cheek & Jones, 2009).

! NURSING SAFETY PRIORITY

Critical Rescue

At a minimum, the patient's identity, correct side and site, correct patient position, and agreement on the proposed procedure must be verified by all members of the surgical team.

Patient Self-Determination. Patients receiving medical care have the right to have or to initiate advance directives, such as a living will or durable power of attorney, as mandated by the Patient Self-Determination Act. Advance directives provide legal instructions to the health care providers about the patient's wishes and are to be followed. *Surgery does not provide an exception to a patient's advance directives or living will (AORN, 2010c).* Chapter 9 discusses advance directives in more detail.

? NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

The client scheduled to have surgery today cannot read or write. The surgeon obtaining the consent wants to have the client's spouse sign the consent instead. What is the nurse's best action?

- A. Nothing; a signed informed consent statement does not need to be obtained from this client.
- B. Locate the spouse because the informed consent statement must be signed by the client's closest relative.
- C. Remind the surgeon that the client may sign the informed consent statement with an X in front of two witnesses.
- D. Notify the administration because the court must appoint a legal guardian to represent the client's best interests and give consent for all surgical procedures.

Implementing Dietary Restrictions. Regardless of the type of surgery and anesthesia planned, the patient is restricted to NPO status before surgery. **NPO** means no eating, drinking (including water), or smoking (nicotine stimulates gastric secretions). The exact amount of time a

patient must be NPO before surgery is controversial. Patients, especially older adults, who fast for 8 or more hours may have imbalances of fluids, electrolytes, and blood glucose levels. The American Society of Anesthesiologists (ASA) recommends a reduced NPO time—6 or more hours for easily digested solid food and 2 hours for clear liquids (*American Society of Anesthesiologists Task Force, 1999; Crenshaw & Winslow, 2008*). A major problem is that these guidelines for duration of fasting have not been implemented universally (see the **Evidence-Based Practice box** at right).

NPO status ensures that the stomach contains a limited volume of gastric secretions, which decreases the risk for aspiration. Outpatients and patients who are scheduled for admission to the hospital on the same day that surgery is performed must receive written and oral instructions about when to begin NPO status.

! NURSING SAFETY PRIORITY

Action Alert

Emphasize the importance of adherence to the prescribed NPO restriction. Failure to adhere can result in cancellation of surgery or increase the risk for aspiration during or after surgery.

Administering Regularly Scheduled Drugs. On the day of surgery, the patient's usual drug schedule may need to be altered. Consult the medical physician and the anesthesia provider for instructions about drugs such as those taken for diabetes, cardiac disease, or glaucoma, as well as regularly scheduled anticonvulsants, antihypertensives, anticoagulants, antidepressants, and corticosteroids. The physician may prescribe some drugs, including over-the-counter drugs such as aspirin, and herbal supplements to be stopped until after surgery. Other drugs may be given IV to maintain the drug level in the blood. *Drugs for cardiac disease, respiratory disease, seizures, and hypertension are commonly allowed with a sip of water before surgery.* Some antihypertensive or antidepressant drugs are withheld on the day of surgery to reduce adverse effects on blood pressure during surgery. Even when beta-blockers are not part of a patient's usual medications, they may be prescribed for some patients who are at risk for cardiac problems. Check with the health care provider, surgeon, or anesthesia provider to determine whether a specific patient requires perioperative therapy with beta-blocking drugs, as recommended by core measures for SCIP CARD-2 (see *Table 16-1*).

The patient with diabetes who takes insulin may be given a reduced dose of intermediate- or long-acting insulin based on the blood glucose level or may be given regular (fast-acting) insulin in divided doses on the day of surgery. As an alternative, an IV infusion of 5% dextrose in water may be given with the insulin to prevent low blood sugar during surgery. Because of the many treatment approaches to diabetes, clarify drug and IV prescriptions with the physician. (See *Chapter 67* for more information about diabetes.)

Intestinal Preparation. Bowel or intestinal preparations are performed to prevent injury to the colon and to reduce the number of intestinal bacteria. Evacuation of the bowel is needed when a patient is having major abdominal, pelvic, perineal, or perianal surgery. The surgeon's preference and the type of surgical procedure determine the type of bowel

EVIDENCE-BASED PRACTICE

How Long Will It Take for Guideline Implementation?

Crenshaw, J., & Winslow, E. (2008). Preoperative fasting duration and medication instruction: Are we improving? *AORN Journal*, 88(6), 963-976.

More than a decade ago, the American Society of Anesthesiologists examined the evidence for long duration of fasting (10 to 12 hours) before scheduled surgery and generated new guidelines for shortening the fasting duration for healthy adults. These landmark guidelines recommend a minimum fast of 2 hours for clear liquids and an 8-hour fast for a regular meal of solid food as being sufficient for the prevention of intraoperative regurgitation and aspiration. In addition, the guidelines indicate that important regularly scheduled oral medications, such as those for asthma control or hypertension and cardiac drugs, are permitted anytime before surgery with a small sip of water.

A variety of research reports and previous meta-analyses regarding duration of preoperative fasting as well as a comparison study indicate that implementation of the guidelines for shortened duration of fasting is not widespread. Most patients are still instructed to adhere to an NPO-after-midnight status, which often results in excessive fasting durations between 12 and 15 hours. In addition, although more patients are being instructed to take their important oral drugs, this practice is still not universal. The major barrier to guideline implementation is failure of surgeons and nurses to communicate during preoperative teaching both the shorter duration fasting and the importance of taking some oral medications during the fast. The authors indicate this failure appears to be related not just to being uninformed of the guidelines but, instead, has multiple roots, including resistance to taking the time to individualize patient teaching. However, when approached, surgeons consistently stated they would support whatever the anesthesiologists deemed best practice for preoperative fasting duration.

Level of Evidence: 1

The study is a comparison study of instruction practices before surgery between the years 2000 and 2004. It also includes a meta-analysis of previous findings on the topic of implementation of recommendations of duration of preoperative fasting. Although descriptive rather than experimental in nature, the methods used were appropriate to answer the question posed, and the large numbers of participants resulted in credible evidence to support the need for practice change.

Commentary: Implications for Practice and Research

The major problem interfering with practice change with the issue of duration of preoperative fasting for healthy adults is that the anesthesia provider seldom interacts with the patient until just before surgery, long after the fast has started. It is the nurse and the surgeon who have the initial contact and responsibility for preoperative teaching. When these professionals are not knowledgeable about the guidelines, the instructions for traditional NPO after midnight are reinforced. Having anesthesia providers be involved along with nurses in developing written materials for patient education with regard to preoperative instructions may help reinforce the changes to the professional staff. Starting small, with nurses instructing patients that clear liquids are permitted up to 2 hours before surgery, may begin to break the barriers for best practice. Other suggestions for how nursing and nurses can help speed up implementation of shorter fasting durations include the development of quality improvement projects in which the complications rate of patients who are permitted clear liquids up to 2 hours before surgery is compared with the complications rate of patients who are completely NPO after midnight until surgery.

preparation. Enemas ordered to be given until return flow is clear is a stressful procedure, especially for the older patient. Repeated enemas can cause electrolyte imbalance, fluid volume imbalances, vagal stimulation, and postural (orthostatic) hypotension. Enemas also cause severe anorectal discomfort in patients with hemorrhoids. Some physicians prescribe potent laxatives (e.g., polyethylene glycol electrolyte solution [GoLYTELY]) instead of enemas, especially for older patients. Bowel preparations can be exhausting, and you must take safety precautions to prevent falls.

Skin Preparation. The skin preparation may be embarrassing or uncomfortable for the patient, especially if the surgical site is in a sensitive or private body area. Provide a warm, comfortable, and private environment during the procedure. The skin is the body's first line of defense against infection. A break in this barrier increases the risk for infection, especially for older patients. Skin preparation before surgery is the first step to reduce the risk for surgical site infection (AORN, 2010d).

One or two days before the scheduled surgery, the surgeon may ask the patient to shower using an antiseptic solution. Instruct the patient to be especially careful to clean around the proposed surgical site. If the patient is hospitalized before surgery, showering and cleaning are repeated the night before surgery or in the morning before transfer to the surgical suite. This cleaning reduces contamination of the surgical field and reduces the number of organisms at the site (Roesler et al., 2010). Remove any soil or debris from the surgical site and surrounding areas.

Factors that predispose to wound contamination and surgical site infection include bacteria found in hair follicles, disruption of the normal protective mechanisms of the skin, and nicks in the skin. Shaving of hair creates the potential for infection. Hair clipping with electrical clippers and depilatories are to be used for hair removal as required by The Joint Commission's NPSGs. This type of skin preparation is part of the Surgical Care Improvement Project (SCIP) core measures for SCIP Inf-6 (see Table 16-1).

The Centers for Disease Control and Prevention (CDC) recommends that if shaving is necessary, the hair should be removed using disposable sterile supplies and aseptic principles *immediately* before the start of the surgical procedure. If needed, shaving is performed in the treatment room, the holding area of the operating suite, or the operating room (OR). Fig. 16-3 shows areas of hair removal for various surgical procedures.

Preparing the Patient for Tubes, Drains, and Vascular Access. Prepare the patient for possible placement of tubes, drains, and vascular access devices. Preparation reduces the patient's anxiety and fear and the family's negative reaction. Be careful not to scare the patient while providing information about the purpose of each tube.

Tubes of all sorts are common after surgery. The patient may need an indwelling urinary (Foley) catheter before, during, or after surgery to keep the bladder empty and to monitor kidney function. The patient having abdominal or genitourinary surgery usually has a Foley catheter.

A nasogastric (NG) tube may be inserted before abdominal surgery to decompress or empty the stomach and the upper bowel. More often, however, the tube is placed after the induction of anesthesia, when insertion is less disturbing to the patient and is easier to perform.

Drains are often placed during surgery to help remove fluid from the surgical site. Some drains are under the dressing; others are visible and require emptying. Drains come in various shapes and sizes (see Chapter 18). Inform the patient that drains are often used routinely and that generally they are not painful but may cause some discomfort. Discuss the reasons drains should not be kinked or pulled.

Vascular access is placed for patients receiving a general anesthetic and for most patients receiving other types of anesthetics. Access is needed to give drugs and fluids before, during, and after surgery. Patients who are dehydrated or are at risk for dehydration may receive fluids before surgery.

NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

The client is NPO for surgery scheduled to occur in 4 hours. It is now 9 AM, and the client's regularly prescribed oral drugs (digoxin 0.125 mg, docusate [Colace] 300 mg, and ferrous fumarate [Feostat] 325 mg) are due to be administered. The physician will not be available until the time of surgery. What is the nurse's best action?

- A. Administer digoxin with minimal water and hold the other drugs.
- B. Administer all medications parenterally.
- C. Administer all medications orally.
- D. Hold all medications.

CONSIDERATIONS FOR OLDER ADULTS

Older adult patients are at greater risk for dehydration because their fluid reserves are lower than those of young or middle-aged adults. Carefully monitor older adult patients and patients with cardiac disease receiving IV fluids. (See Chapter 15 for more information on IV therapy.)

The IV access is usually placed in the arm using a large-bore, short catheter (e.g., 18-gauge, 1-inch catheter) or placed in the back of the hand using a smaller-bore (20-gauge) catheter. A larger vein provides the least resistance to fluid or blood infusion, especially in an emergency when rapid infusions may be needed. Depending on the patient's needs and the facility's policies, the IV access can be placed before surgery when the patient is in the hospital room, in the holding or admission area of the surgical suite, or in the OR.

Postoperative Procedures and Exercises. Teach the patient and family members about exercises and procedures (e.g., checking dressings, obtaining vital signs frequently) to be performed after surgery. Family members can be helpful in reminding patients to perform these exercises. Teaching before surgery reduces apprehension and fear, increases cooperation and participation in care after surgery, and decreases respiratory and vascular complications. When the fear or anxiety level is high, explore the patient's feelings before discussing procedures.

Discussion, demonstration with return demonstration, and practice by the patient aid in the ability to perform various breathing (Chart 16-5) and leg (Chart 16-6) exercises after surgery. Stress the need to begin exercises early in the recovery phase and to continue them, with 5 to 10 repetitions each, every 1 to 2 hours after surgery for at least the first 48 hours. Explain that the patient may need to be awakened for these activities.

FIG. 16-3 Skin preparation of common surgical sites. *Shaded areas* indicate preparation areas.

CHART 16-5 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Perioperative Respiratory Care

Deep (Diaphragmatic) Breathing

1. Sit upright on the edge of the bed or in a chair, being sure that your feet are placed firmly on the floor or a stool. (After surgery, deep breathing is done with the patient in Fowler's position or in semi-Fowler's position.)
2. Take a gentle breath through your mouth.
3. Breathe out gently and completely.
4. Then take a deep breath through your nose and mouth, and hold this breath to the count of five.
5. Exhale through your nose and mouth.

Expansion Breathing

1. Find a comfortable upright position, with your knees slightly bent. (Bending the knees decreases tension on the abdominal muscles and decreases respiratory resistance and discomfort.)
2. Place your hands on each side of your lower rib cage, just above your waist.
3. Take a deep breath through your nose, using your shoulder muscles to expand your lower rib cage outward during inhalation.
4. Exhale, concentrating first on moving your chest, then on moving your lower ribs inward, while gently squeezing the rib cage and forcing air out of the base of your lungs.

Splinting of the Surgical Incision

1. Unless coughing is contraindicated, place a pillow, towel, or folded blanket over your surgical incision and hold the item firmly in place.
2. Take three slow, deep breaths to stimulate your cough reflex.
3. Inhale through your nose, and then exhale through your mouth.
4. On your third deep breath, cough to clear secretions from your lungs while firmly holding the pillow, towel, or folded blanket against your incision.

Procedures and Exercises to Prevent Respiratory Complications. Breathing exercises include deep, or diaphragmatic, breathing to enlarge the chest cavity and expand the lungs. After you demonstrate and explain the technique, urge the patient to practice the five steps of deep breathing.

For patients with chronic lung disease or limited chest expansion, as seen in older patients because of the aging process, expansion breathing exercises are useful. For the patient having chest surgery, expansion breathing exercises strengthen accessory muscles and are started before surgery. Expansion breathing may be used after surgery during chest physiotherapy (percussion, vibration, postural drainage) to help loosen secretions and maintain an adequate air exchange.

Incentive spirometry is another way to encourage the patient to take deep breaths. Its purpose is to promote complete lung expansion and to prevent pulmonary problems. Various types of incentive spirometers are available; Fig. 16-4 shows a patient using one type. With all types, the patient must be able to seal the lips tightly around the mouthpiece, inhale spontaneously, and hold his or her breath for 3 to 5 seconds for effective lung expansion. Goals (e.g., attaining specific volumes) can be set according to the patient's ability and the type of incentive spirometer. Seeing a light move up a column or a bellows expanding reinforces and motivates the patient to continue performance.

FIG. 16-4 A patient using an incentive spirometer.

Coughing and splinting may be performed along with deep breathing every 1 to 2 hours after surgery. The purposes of coughing are to expel secretions, keep the lungs clear, allow full aeration, and prevent pneumonia and atelectasis. Coughing may be uncomfortable for the patient, but when performed correctly, it should not harm the incision. Splinting (i.e., holding) the incision area provides support, promotes a feeling of security, and reduces pain during coughing. The proper technique for splinting the incision site and coughing is described in Chart 16-5. A folded bath blanket or pillow is helpful to use as a splint. Cardiac patients may receive their own heart-shaped pillow for splint use.

The use of routine coughing exercises after surgery is controversial. Some surgeons believe coughing may harm the surgical wound and that it would be better to use other, safer measures for lung hygiene, such as deep breathing and incentive spirometer exercises. When routine coughing exercises should be avoided for a specific patient, such as after a hernia repair or craniotomy, the surgeon usually writes a “do not cough” prescription.

Procedures and Exercises to Prevent Cardiovascular Complications. Venous stasis leading to thromboembolism (VTE) (a group of disorders that includes deep vein thrombosis [DVT] and pulmonary embolism [PE]) are potential but avoidable complications of surgery. These problems can lead to a pulmonary embolus (PE) if the blood clot breaks off and travels to the lungs. Patients at greater risk for VTE:

- Are obese
- Are older than 40 years
- Have cancer
- Have decreased mobility or are immobile
- Have a spinal cord injury
- Have a history of VTE, PE, varicose veins, or edema
- Are taking oral contraceptives
- Smoke
- Have decreased cardiac output
- Have hip fracture or total hip or total knee surgery

Always assess for VTE before surgery. Sudden swelling in one leg is a common physical finding of VTE. A patient may feel a dull ache in the calf area that becomes worse with ambulation. A careful assessment and timely intervention may prevent the fatal complication of pulmonary embolism.

Because surgical-related VTE can be prevented, prophylaxis is required by the Surgical Care Improvement Project

CHART 16-6 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Postoperative Leg Exercises**Exercise No. 1**

1. Lie in bed with the head of your bed elevated to about 45 degrees.
2. Beginning with your right leg, bend your knee, raise your foot off the bed, and hold this position for a few seconds.
3. Extend your leg by unbending your knee, and lower the leg to the bed.
4. Repeat this sequence four more times with your right leg; then perform this same exercise five times with your left leg.

**Exercise No. 2**

1. Beginning with your right leg, point your toes toward the bottom of the bed.
2. With the same leg, point your toes up toward your face.
3. Repeat this exercise several times with your right leg; then perform this same exercise with your left leg.

**Exercise No. 3**

1. Beginning with your right leg, make circles with your ankle, first to the left and then to the right.
2. Repeat this exercise several times with your right leg; then perform this same exercise with your left leg.

**Exercise No. 4**

1. Beginning with your right leg, bend your knee and *push* the ball of your foot into the bed or floor until you feel your calf and thigh muscles contracting.
2. Repeat this exercise several times with your right leg; then perform this same exercise with your left leg.

(SCIP) core measures (see Table 16-1). All patients should be evaluated for VTE risk based on history, type and duration of surgery, and expected time of immobilization after surgery. VTE prophylaxis may involve devices and drug therapy, depending on a specific patient's evaluated risk. Devices may be used during and after surgery along with leg exercises and early ambulation to promote venous return. Specific interventions depend on the patient's risk factors.

Antiembolism stockings (TED or Jobst stockings) and elastic (Ace) wraps provide graduated compression of the legs, starting at the end of the foot and ankle. Measure the patient's leg length and circumference before ordering the stocking size. Elastic wraps are used when the legs are too large or too small for the stockings. Assist the patient in applying the stockings or wraps, and ensure that they are neither too loose (are ineffective) nor too tight (inhibit blood flow). They need to be worn properly and should be removed one to three times per day for 30 minutes for skin inspection and care.

Pneumatic compression devices enhance venous blood flow by providing intermittent periods of compression on the legs (Cawley, 2008). Measure the patient's legs, and order the correct size. Place the boots on the patient's legs, and then set and check the compression pressures (usually 35-55 mm Hg).

Fig. 16-5 shows various types of sequential compression devices. Antiembolism stockings may be worn in addition to the boots and may reduce some of the uncomfortable sensations of the boots (e.g., itching, sweating, heat).

Leg exercises also promote venous return. Teach the leg exercises outlined in Chart 16-6, and then urge the patient to practice these exercises before surgery. The exercises are important, even when other devices are used.

Mobility soon after surgery (early ambulation) has many cardiovascular and other benefits (Winkelman, 2009). It stimulates intestinal motility, enhances lung expansion, mobilizes secretions, promotes venous return, prevents joint rigidity, and relieves pressure. For most types of surgery, teach the patient to turn at least every 2 hours after surgery while confined to bed. Teach patients how to use the bed siderails safely for turning and how to protect the surgical wound (splinting) when turning. Assure patients that assistance and pain drugs will be given as needed to reduce any anxiety and pain they may have with this activity.

For certain surgical procedures, such as some brain, spinal, and orthopedic procedures, the surgeon may prescribe turning restrictions. Ask the surgeon about other interventions to prevent complications of immobility in patients with

FIG. 16-5 Examples of external pneumatic compression devices used to promote venous return and prevent venous thromboembolism (VTE). **A**, Kendall SCD machine, sleeves, and TED stockings. **B**, Venodyne pneumatic compression system. **C**, Flowtron DVT calf garments.

turning restrictions. Inform the patient of anticipated turning restrictions during teaching before surgery.

Most patients are allowed and encouraged to get out of bed the day of or the day after surgery. Assist the patient into a chair or with ambulation after the surgery, the next day, or when the surgeon specifies. If a patient must remain in bed, help him or her turn, deep breathe, and perform leg exercises at least every 2 hours to prevent complications from immobility.

Minimizing Anxiety

Planning: Expected Outcomes. Before surgery, the patient is expected to have manageable anxiety as indicated by consistently demonstrating these behaviors:

- Expressing a reduced level of anxiety
- Showing an absence of body language indicators of anxiety (e.g., hand wringing, facial tension, restlessness, dilated pupils, sweating, elevated blood pressure, elevated pulse rate)

Interventions. Anxiety often causes restlessness and sleeplessness. The patient may perceive the surgical experience as a threat to life and function. Assess the patient's level of

anxiety, as discussed on p. 247 in the Psychosocial Assessment section. Interventions such as teaching and communicating with the patient before surgery, enabling the patient to use previously successful coping mechanisms, and giving anti-anxiety drugs help reduce the anxiety. Incorporate available support systems into the plan of care.

Preoperative teaching involves first assessing the patient's knowledge about the surgical experience (see pp. 248 and 250 in the Providing Information section) and then providing factual information to promote the patient's understanding. Allow ample time for questions. Respond to the questions accurately, and refer unanswered questions to the proper person. During the discussion, continually assess the patient's responses and anxiety level. Be careful not to provide information that might increase anxiety. Patients have ranked psychosocial support as the most important part of preoperative teaching. The informed, educated patient is better able to anticipate events and maintain self-control and is thus less anxious.

Encouraging communication by having the patient state feelings, fears, and concerns can help reduce anxiety. Use an honest and open approach so that the patient can express

feelings freely without fear of ridicule or judgment. Keep the patient informed by clarifying information, answering questions, and allaying fears about the surgery.

Promoting rest is helpful because the stress and anxiety of impending surgery often interfere with the patient's ability to sleep and rest the night before surgery. The period before surgery is physically and emotionally stressful. To help the patient relax, determine what he or she usually does to relax and fall asleep. If the patient is able, urge him or her to continue these methods of relaxation. A back rub is relaxing and can be performed by a nurse, UAP, or family member. The surgeon may prescribe a sedative or hypnotic drug to help the patient be well rested for surgery.

Distraction may be used as an intervention for anxiety, especially in the 24 hours immediately before surgery. Listening to music may decrease anxiety, as may watching television, reading, or visiting with family members.

Teaching family members helps reduce anxiety by increasing the likelihood of support and involvement in the patient's care. Assess the readiness and desire of the family to take an active part in the patient's care. A positive sign of family interest is that of members asking questions about the surgical experience. After family readiness is determined, keep family members informed and encourage their involvement in all aspects of education. Emphasize the important role of the family before surgery, but guide discussions and practice sessions so that family members do not dominate the sessions. Family members can encourage and help the patient practice exercises to be performed after surgery.

Inform the family of the time for surgery, if known, and of any schedule changes. If the patient is an outpatient, provide clear directions to the patient and family regarding any specific night-before procedures, what time and where to report, and what to bring with them. Encourage the family to stay with the patient before surgery for support.

Most families are anxious about the surgery planned for their loved one. To reduce their anxiety, explain the routines expected before, during, and after surgery. Tell the family that after the patient leaves the hospital room or admission area, there is usually a 30- to 60-minute preparation period in the operating area (holding room, treatment area) before the surgery actually begins. After surgery, the patient is taken to the postanesthesia care unit (PACU) for 1 to 2 hours before returning to the hospital room or discharge area. Tell the family about the best place to wait for the patient or surgeon according to the facility's policy and the physician's preference. Many hospitals and surgical centers have surgical waiting areas so that families can wait in comfortable surroundings and be easily located when the procedure is

completed. Often families are provided with a beeper to let them know when to report to a specific area to receive updates about the patient's status, meet with the surgeon, or see the patient.

Preoperative Chart Review

Review the patient's chart to ensure that all documentation, preoperative procedures, and orders are completed. Check the surgical informed consent form and, if indicated, any other special consent forms to see that they are signed and dated and that they contain the witnesses' signatures. Confirm that the scheduled procedure, including the identification of left versus right when necessary, is what is listed on the consent form. Even though it might be obvious, inform the patient that the area for surgery will be marked before the procedure begins. If possible, encourage the patient to assist with the marking, as suggested by The Joint Commission's NPSGs. Document allergies according to facility policy. Accurate measuring and recording of height and weight are important for proper dosage of the anesthetic agents. Ensure that the results of all laboratory, radiographic, and diagnostic tests are on the chart. Document any abnormal results, and report them to the surgeon and the anesthesia provider. If the patient is an autologous blood donor or has had directed blood donations made, those special slips must be included in the chart. Record a current set of vital signs (within 1 to 2 hours of the scheduled surgery time), and document any significant physical or psychosocial observations.

Report special needs, concerns, and instructions (advance directives) to the surgical team, as required by The Joint Commission's NPSGs. For example, advise the surgical team if the patient is a member of Jehovah's Witnesses and does not accept blood products or if the patient is hard of hearing and does not have his or her hearing aid. This information assists the surgical team in providing continuity of care while the patient is in the surgical area.

Preoperative Patient Preparation

Facilities usually require the patient to remove most clothing and wear a hospital gown into the OR; however, underwear may be worn in above-the-waist surgery and socks may be worn, except in foot or leg surgery. If prescribed by the surgeon, apply antiembolism stockings or pneumatic compression devices before surgery. In some ambulatory settings, such as for cataract surgery, no or minimal clothes are removed.

Patients are advised to leave all valuables at home. If he or she has valuables, including jewelry, money, or clothes, they are given to a family member or locked in a safe place, according to the facility's policy. If rings cannot be removed, tape them in place. Depending on the type and location of surgery, pierced jewelry may need to be removed. Religious emblems may be pinned or fastened securely to the patient's gown. Some facilities have paper emblems from a religious leader.

The patient wears an identification band that clearly gives the first and last name, hospital number, physician, and birth date. An additional bracelet, usually red, identifies any allergies. A bracelet indicating that a blood sample for type and screen has been drawn may be worn, depending on the facility's policy.

If dentures are to be removed, including partial dental plates, place them in a labeled denture cup. Denture removal

DECISION-MAKING CHALLENGE

Safety

The patient is a 70-year-old woman scheduled to have knee surgery. She has signed her consent form for a right total knee replacement. After confirming the identity of the patient and the correct site, side, and procedure, you inform her that the surgeon will be marking the operative site. The patient states that she wants her grandchild to mark the site because she promised him the chance to draw on grandma's leg.

1. How would you respond to the patient's request?
2. How can you include the grandchild in the process in order not to disregard the patient's request?

is a safety measure to prevent aspiration and obstruction of the airway. If a patient has any capped teeth, document this finding on the checklist.

All prosthetic devices, such as artificial eyes and limbs, are removed and given to a family member or safely stored, as are contact lenses, glasses, wigs, and toupees. Check and remove hairpins and clips, which can conduct electrical current used during surgery and cause scalp burns.

Some facilities allow hearing aids in the surgical suite to help communication before and after surgery. If the patient is sent to surgery with a hearing aid, communicate this to the surgical nurse to prevent accidental loss of or damage to the device. Some facilities allow dentures, wigs, and glasses to be worn into the operating suite to prevent embarrassment to the patient. These items are removed when absolutely necessary.

The removal of fingernail polish or artificial nails is controversial. Polish and artificial nails have been thought to affect the accuracy of pulse oximetry readings. Recent studies have indicated that pulse oximetry readings taken on fingers are affected by brown or blue polish but not by red or lighter color polish. In addition, pulse oximetry does not have to be measured on fingers only. Some facilities still require that at least one artificial nail must be removed to monitor oxygen saturation by pulse oximetry.

After the patient is prepared for surgery and the operating suite is ready to receive him or her, ask him or her to empty the bladder. This action prevents incontinence or overdistention and is a starting point for intake and output measurement. A full bladder may hinder access to the surgical site. Answer questions, offer reassurance as needed, and give prescribed drugs.

Preoperative Drugs

Preoperative drugs may be prescribed regardless of the type of planned anesthesia. Various drugs reduce anxiety, promote relaxation, reduce nasal and oral secretions, prevent laryngospasm, reduce vagal-induced bradycardia, inhibit gastric secretions, and decrease the amount of anesthetic needed for the induction and maintenance of anesthesia. Drug selection is based on the patient's age, physical and psychological condition, medical history, and height and weight; other drugs the patient takes routinely; test results; and the type and extent of the planned surgical procedure. If more than one response is required, combination therapy may be prescribed.

Drug types for preoperative preparation may include sedatives (e.g., hydroxyzine [Atarax, Vistaril]); hypnotics (e.g., lorazepam [Ativan]); anxiolytics (e.g., midazolam [Versed]); opioid analgesics (e.g., morphine, hydromorphone); and an anticholinergic agent (e.g., atropine). Other specific-purpose drugs also may be added. For example, if rapid emptying of the stomach is needed, metoclopramide (Reglan) may be prescribed. When procedures are long or stress ulcers are likely, an H₂ histamine blocker (e.g., cimetidine [Tagamet]; ranitidine [Zantac]) is used (DeLamar, 2007).

Preoperative drugs may be given when the patient is “on call” to the surgical suite. After positively identifying the patient as required by The Joint Commission's NPSGs, (using the armband and asking the patient to state his or her name) and making sure the operative permit is signed, give the correct drugs in the correct doses. Then raise the siderails,

place the call light within easy reach of the patient, and remind him or her not to try to get out of bed. Place the bed in a low position. Tell the patient that he or she may become drowsy and have a dry mouth as a result of the drugs.

A more common practice is for the preoperative drugs to be given *after* the patient is transferred to the operating area (DeLamar, 2007). This practice permits the surgical team and anesthesia personnel to make more accurate assessments and have last-minute discussions with a patient not yet affected by drugs. In addition, after the patient is in the preoperative area, drugs can be given by the IV route. Monitoring equipment such as continuous pulse oximetry and ECG are more readily available in this area. The oral or IM route is used less often because of variable absorption rates. The surgeon may order a prophylactic antibiotic to be given right before or during surgery to reduce the risk for a surgical site infection, as suggested by The Joint Commission's NPSGs. When needed, the antibiotic is given within 60 minutes before the incision is made, as mandated by the Surgical Care Improvement Project (SCIP) core measures, SCIP Inf-1 (see Table 16-1).

Patient Transfer to the Surgical Suite

In the immediate preoperative period, review and update the patient's chart, reinforce teaching, ensure that the patient is correctly dressed for surgery, and give prescribed preoperative drugs. Use a preoperative checklist for a smooth, efficient transfer to the surgical suite (Fig. 16-6). The patient, along with the signed consent form, the completed preoperative checklist, the chart, and the patient identification card, is transported to the surgical suite.

Most patients in the hospital setting are transferred to the surgical suite on a stretcher with the siderails up. In special circumstances (e.g., patients requiring traction, those having orthopedic surgery, those who should be moved as little as possible), the patient is transferred in the hospital bed. Other factors that influence the decision to transfer in a bed are the patient's age, size, and physical condition. In ambulatory settings, patients either walk or are transferred to the surgical suite on a stretcher or in a wheelchair.

DECISION-MAKING CHALLENGE

Teamwork and Collaboration

You are about to send the patient, described earlier in the Decision-Making Challenge on p. 259, to the surgical suite. A partner of the operating surgeon, who has not met the patient, proceeds to implement the time-out, which provides a final assessment that includes that the correct patient, site, side, and procedure are identified. The patient is concerned, stating she thought that the surgeon would be here for this part.

1. As the patient advocate, how would you proceed with the time-out?
2. Which measures should the facility have in place to promote best practices for this process?
3. What steps can be taken to prevent such an occurrence in the future?

EVALUATION: OUTCOMES

Evaluate the care of the preoperative patient based on the identified patient problems. The expected outcomes include that the patient:

- States understanding of the informed consent and preoperative procedures

- Has reduced anxiety

Specific indicators for these outcomes are listed for each patient problem in the Planning and Implementation section (see earlier).

GET READY FOR THE NCLEX® EXAMINATION!

KEY POINTS

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Ask the patient if an advance directive has been completed.
- Ask the patient to explain in his or her own words what surgical procedure is being done and why.
- If the patient's explanation of the scheduled surgery is not consistent with the documentation, notify the surgeon and request that he or she speak to the patient.
- Use at least two appropriate identifiers (e.g., hospital number, the identification band, asking the patient to state his or her name) to identify the patient. *Do not use room number or bed number to identify the patient.*
- Ensure that the patient is wearing proper identification.
- Ensure that the patient is not asked to sign an operative permit or any other legal document after the preoperative drugs have been given.
- After the patient has received preoperative drugs, keep the siderails up and the bed in the low position.
- Communicate to the surgeon and anesthesia personnel any physical or laboratory change that may alter the patient's response to drugs, anesthesia, or surgery.

Health Promotion and Maintenance

- Teach patients about dietary restrictions and preoperative preparations.

- Teach the patient specific interventions to perform after surgery to prevent complications (incision splinting, deep-breathing exercises, range-of-motion exercises—as described in [Charts 16-5 and 16-6](#)).

Psychosocial Integrity

- Pace your interview to match the learning needs and style of the individual patient.
- Encourage the patient to express his or her feelings regarding the surgical procedure or its possible outcome.
- Explain and provide written information for all diagnostic procedures, restrictions, and follow-up care to the patient and his or her family.
- Communicate to the surgeon and anesthesia personnel any concerns or fears the patient has.

Physiological Integrity

- Check that documentation for any procedure to be performed on one of a paired organ or extremity clearly indicates which organ or extremity is involved.
- If required, ensure that dentures and any other personal items are removed from the patient before he or she is transferred to the surgical suite.

Care of Intraoperative Patients

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Use appropriate patient identifiers when administering drugs or marking surgical sites.
2. Verify that the patient has given informed consent for the surgical procedure.
3. Examine individual patient factors for potential threats to safety, especially for older adults.
4. Differentiate the roles and responsibilities of intraoperative personnel.
5. Understand the principles of infection prevention as they apply to aseptic technique in setting up a sterile field.
6. Explain correct technique to apply and remove surgical attire.
7. Understand the nurse's role in monitoring all OR personnel for possible breaks in sterile technique.

Psychosocial Integrity

8. Apply nursing interventions to reduce patient and family anxiety.

9. Explain procedures to ensure the identity of the patient and the accuracy of the planned surgical procedure.
10. Act as a patient advocate with regard to patients' rights, informed consent, and advance directives.
11. Apply interventions to ensure the patient's safety and dignity during an operative procedure.

Physiological Integrity

12. Assess patients for specific problems related to positioning during surgical procedures.
13. Understand anatomic principles for modifying patient positioning and OR bed padding to prevent skin breakdown, promote comfort, and prevent positioning injury during surgical procedures.
14. Coordinate appropriate care for the patient with malignant hyperthermia.

The intraoperative period begins when the patient enters the surgical suite and ends at the time of transfer to the postanesthesia recovery area, same-day surgery unit, or the intensive care unit. The main concerns of perioperative nurses are the safety and advocacy for the patient during surgery. Nursing observations and actions can prevent, reduce, control, and manage many hazards. Once in the operating room (OR), the patient is at risk for infection, impaired skin integrity, increased anxiety, altered body temperature, and injury

related to positioning and other hazards. The surgical phase is filled with unfamiliar experiences and uncertain outcomes. Nursing care during this period is critical because the patient's physical needs, spiritual needs, comfort, safety, dignity, and psychological status depend on the perioperative nurse. Specific procedures and policies may differ among agencies but should all reflect the perioperative standards and recommended practices as published by the [Association of peri-Operative Registered Nurses \(AORN\)](#) (2010a). Perioperative

nurses practice within a specific, patient-focused model that incorporates professional practice with attainable, measurable outcomes.

OVERVIEW

MEMBERS OF THE SURGICAL TEAM

The surgical team consists of the surgeon, one or more surgical assistants, the anesthesia provider, and the OR nursing staff. Perioperative, or OR, nurses include the holding area nurse, circulating nurse, scrub nurse or a non-nurse “scrub person,” and specialty nurse. The number of assistants, circulating nurses, and scrub nurses depends on the complexity and projected length of the surgical procedure. For some minor procedures, only a circulating nurse and scrub person may be needed in addition to the surgeon. More complex procedures may require additional nursing staff to either circulate or scrub.

Surgeon and Surgical Assistant

The *surgeon* is a physician who assumes responsibility for the surgical procedure and any surgical judgments about the patient. The *surgical assistant* might be another surgeon (or physician, such as a resident or intern) or an advanced practice nurse, physician assistant, certified registered nurse first assistant (CRNFA), or surgical technologist. Under the direction of the surgeon and within the legal scope of practice for each state, the assistant may hold retractors, suction the wound (to improve viewing of the operative site), cut tissue, suture, and dress wounds.

Anesthesia Providers

The *anesthesiologist* is a physician who specializes in giving anesthetic agents. A *certified registered nurse anesthetist (CRNA)* is a registered nurse with additional education and credentials who delivers anesthetic agents under the supervision of an anesthesiologist, surgeon, dentist, or podiatrist. The anesthesia provider gives anesthetic drugs to induce and maintain anesthesia and delivers other drugs as needed to support the patient during surgery.

The anesthesia provider monitors the patient during surgery by assessing and monitoring:

- The level of anesthesia (i.e., by using a peripheral nerve stimulator or electroencephalogram [EEG] bispectral analysis)
- Cardiopulmonary function (using electrocardiographic [ECG] monitoring, pulse oximetry, end-tidal carbon dioxide monitoring, arterial blood gases [ABGs], and hemodynamic monitoring via arterial lines and/or pulmonary artery catheters)
- Capnography (monitors ventilation for non-intubated patients)
- Vital signs
- Intake and output

Depending on the patient's needs, anesthesia personnel give IV fluids, including blood and blood products.

Perioperative Nursing Staff

Perioperative, or OR, staff have several roles during surgery, depending on their education, experience, skill, and job responsibilities. Regardless of their role, the OR nurse uses

clinical decision-making skills, develops a plan of nursing care, and coordinates care delivery to patients and their family members.

Holding area nurses work in those operating suites that have a presurgical holding area next to the main ORs. The patient waits in this area until the OR is ready. The holding area nurse coordinates and manages the care while the patient is in this area. Responsibilities include greeting the patient on arrival, reviewing the medical record and preoperative checklist, verifying that the operative consent forms are signed, and documenting the risk assessment (Fig. 17-1). This nurse also assesses the patient's physical and emotional status, gives emotional support, answers questions, and provides additional education as needed.

The holding area is busy, with many staff members performing different procedures before surgery (e.g., starting IV lines, inserting epidural catheters). The holding area nurse promotes an atmosphere of comfort, privacy, and confidentiality. Depending on the facility's policy, family members may wait with the patient.

Circulating nurses or “circulators” are registered nurses who coordinate, oversee, and are involved in the patient's nursing care in the OR. The circulating nurse's actions are vital to the smooth flow of events before, during, and after surgery. He or she is responsible for coordinating all activities within that particular OR. The circulator sets up the OR and ensures that supplies, including blood products and diagnostic support, are available as needed. All anticipated equipment is gathered and inspected by the circulator to make certain that it is safe and functional before the surgery. Depending on the procedure and position required, the circulator makes up the operating bed (OR table) with gel pads (to prevent pressure ulcers), safety straps and armboards (for patient positioning), and either heating pads under the sheets or disposable warming blankets placed over the patient as indicated (to prevent hypothermia) (Weirich, 2008).

If there is no holding area nurse, the circulator assumes the responsibilities of that nursing role as well. Even when there is a holding area nurse, The Joint Commission's National Patient Safety Goals (NPSGs) require that the circulator also greets the patient and reviews findings with the holding area nurse.

Once the patient is ready to be moved into the OR, the circulating nurse, along with the OR team, assists the patient in transferring to the operating bed. The nurse positions the patient, protecting bony areas with extra padding while providing comfort and reassurance. While observing the patient, the circulating nurse also assists the anesthesia provider with the induction of anesthesia by positioning the patient and applying cricoid pressure, when requested. The circulator then may assist with additional positioning, insert a Foley catheter if needed, apply the grounding pad, test equipment, and “prep” (scrub) the surgical site before the patient is draped with sterile drapes.

Throughout the surgery, the circulating nurse:

- Protects the patient's privacy
- Ensures the patient's safety
- Monitors traffic in the room
- Assesses the amount of urine and blood loss
- Reports findings to the surgeon and anesthesia provider
- Ensures that the surgical team maintain sterile technique and a sterile field

FIG. 17-1 Identification of patient, procedure, and surgical side/sites, and fire risk assessment.

- Anticipates the patient's and surgical team's needs, providing supplies and equipment
- Communicates information about the patient's status to family members during long or unique procedures
- Documents care, events, interventions, and findings

Depending on facility policy, the circulating nurse may record drugs, blood, and blood components given. (This also may be a function of the anesthesia provider.)

Before the procedure is over, the circulating nurse completes documentation in the OR and nursing records,

FIG. 17-2 Setting up the sterile table.

including the presence of drains or catheters, the length of the surgery, and a count of all sponges, “sharp” (needles, blades), and instruments. He or she notifies the postanesthesia care unit (PACU) of the patient’s estimated time of arrival and any special needs.

Scrub nurses or scrub persons set up the sterile table (Fig. 17-2), drape the patient, and hand sterile supplies, sterile equipment, and instruments to the surgeon and the assistant. Knowledge of the surgical procedure allows the scrub person to anticipate which instruments and types of sutures the surgeon will need. Anticipating these needs reduces the duration of anesthesia for the patient. In addition, the surgeon’s anxiety and tension are reduced when the scrub nurse or person is familiar with the procedure and can anticipate and respond accordingly. Throughout the surgical procedure, the scrub person (with the circulating nurse) maintains an accurate count of sponges, sharps, and instruments and amounts of irrigation fluid and drugs used.

A specially trained person who is not a nurse may perform the scrub role. Such people are called *operating room technicians (ORTs)* or *surgical technologists*. Often certified surgical technologists (CSTs) are used in the OR.

Specialty nurses may be in charge of a particular type of surgical specialty (e.g., orthopedic, cardiac, ophthalmologic) and are responsible for nursing care specific to patients needing that type of surgery. The specialty nurse assesses, maintains, and recommends equipment, instruments, and supplies used in that specialty.

If the facility uses laser technology, a nurse specially trained in the use, care, and maintenance of the laser is needed. He or she may be called a *laser specialty nurse* or a *laser nurse coordinator*. (**L**aser is an acronym for **l**ight **a**mplification by the **s**timulated **e**mission of **r**adiation.) A laser gives off a high-powered beam of light that cuts tissue more cleanly than do scalpel blades. This process creates intense heat, rapidly clots blood vessels or tissue, and turns target tissue (e.g., a tumor) into vapor. All personnel must observe safety measures (e.g., wear eye shields, read door signs) during laser procedures to prevent injury to the patient and staff (AORN, 2010h).

NCLEX EXAMINATION CHALLENGE

Psychosocial Integrity

The client brought to the holding area before surgery tells the nurse he has never had surgery before and is afraid of anything “medical.” Which nursing action is most likely to reduce this client’s anxiety?

- A. Administering the preoperative medication as soon as possible.
- B. Assuring the client that his scheduled surgery is routine and that nothing will go wrong.
- C. Determining whether the client wants family members to be with him in the holding area.
- D. Explaining to the client that this hospital’s surgical area is the most technologically advanced in the city.

PREPARATION OF THE SURGICAL SUITE AND TEAM SAFETY

The patient is unable to protect himself or herself during surgery; protection is provided by all members of the surgical team. The OR layout helps prevent infection by reducing contaminants through air exchanges in the room, maintaining recommended temperature and humidity levels, and limiting the traffic and activities in the OR. Safety straps are used for the patient, and the operating bed is locked in place. Blankets or warming units are used to prevent hypothermia, and interventions are used to prevent skin breakdown.

The nurse ensures electrical safety through proper placement of grounding pads and use of electrical equipment that meets safety standards. All equipment used during surgery must be functional and in proper working condition as determined by the safety procedure of that facility. Equipment is cleaned and, when required, sterilized so that it can be used as a part of the procedure. The scrub and circulating nurses together ensure a correct count of surgical instruments, sharps, and sponges. Counts are performed before the procedure, during the procedure as items are added or at the time personnel are relieved from that assignment, at closure of the first layer of the surgical wound, and immediately before complete skin closure (AORN, 2010i; Jackson & Brady, 2008).

Fire prevention and prevention of complications from the use of hazardous or toxic substances are concerns of all OR personnel. Ignition sources, oxidizers, and fuels are present in the OR and increase the risk for fires. Such events are rare but can occur during any kind of procedure. A cool room temperature (between 68° and 73° F [20° and 23° C]) with low humidity (20% to 60%) is optimal. The nurse is aware of emergency measures to take in the event of a fire or spill.

Layout

The surgical suite is located out of the mainstream of the hospital and near the PACU and support services (e.g., blood bank, pathology, and laboratory departments). Traffic flow is patterned to reduce contamination from outside the suite. Within the suite, clean and contaminated areas are separate. The surgical area is divided into three zones—unrestricted, semirestricted, and restricted—to ensure proper movement of patients and personnel.

The size of a surgical suite depends on the size and surgical capabilities of the facility. Most suites contain staff areas as well as areas related to patient care, surgery, and surgical support. Staff areas include locker rooms and staff lounges. Patient care areas include an admission or preoperative

holding area and operating rooms. Surgical support areas include a number of ORs, cabinets for sterile supplies, separate utility rooms for clean and soiled equipment, and a clean linen room.

Fig. 17-3 shows a typical OR. The exact number of tables and equipment used in a room is based on the needs of each patient. A communication system links the OR and the main desk of the surgical suite. The system includes an intercom with separate systems for routine and emergency calls.

New OR designs use computers with the surgical equipment, lights, OR bed, and communications. These “hi-tech” rooms are similar to traditional ORs with the addition of computer equipment and panels. They are larger and more efficient for the surgical team with voice-activated commands operating some equipment that used to require manual operation.

Minimally Invasive and Robotic Surgery

Minimally invasive surgery (MIS) is now a common practice. Once used only for minor procedures and joint surgery, MIS is the preferred technique for many types of surgery, including cholecystectomy, cardiac surgery, splenectomy, and spinal surgery. It is even being used for cancer surgeries, such as the removal of a lung lobe (lobectomy) or even the entire lung (pneumonectomy) and colectomy. Research has verified many benefits of MIS, including reduced surgery time for some surgeries, smaller incisions, reduced blood loss, faster recovery time, and less pain and other discomfort after surgery.

MIS involves making one or more small incisions in the area of the surgery and placing an endoscope through the opening. An **endoscope** is a tube that allows viewing and manipulation of internal body areas (Fig. 17-4). Some endoscopes also magnify the view. These instruments may be rigid, semirigid, or flexible. Some have light sources, whereas others require that a separate light source be inserted into the surgical area. Endoscopes have different names and shapes for different surgical purposes. For example, laparoscopes are used for abdominal surgery, arthroscopes are used for joint surgery, and ureteroscopes are used for urinary tract surgery.

At one time, endoscopes were used only for examination and obtaining small specimens for biopsy. Now, these instruments can be used by surgeons for organ removal, reconstruction, blood vessel grafting, and many other procedures. Cutting, suturing, stapling, cautery, and laser surgery can all be performed through or with endoscopes. An important part of MIS for abdominal surgery, pelvic surgery, and surgery in some other body cavity areas is injecting gas or air into the cavity before the surgery to separate organs and improve visualization. This injection is known as **insufflation** and may contribute to complications and patient discomfort. It is one factor that is considered when deciding whether to perform a procedure by traditional “open” surgery or by endoscopy.

Patient preparation for endoscopic surgery is much the same as the preparation for the same procedure when performed by open surgical methods, especially for abdominal surgery. An endoscopic surgical procedure has a chance for becoming an open surgical procedure depending on what patient-related or procedure-related variables are discovered or develop during the surgery.

Robotic technology is drastically changing how surgery is performed and how the OR is organized. Robotic surgery takes minimally invasive surgery to a new level. Many gynecologic, urologic, and cardiovascular procedures are being performed by using robotics. The robotic system consists of several components (Fig. 17-5). These include a console, surgical arm cart, and video cart. Initially, the surgeon inserts the required instruments and positions the articulating arms; he or she then breaks scrub and performs the surgery while sitting at the console. A three-dimensional (3-D) view of the patient’s anatomy provides the surgeon with precise control and dexterity. The vision cart holds the monitors, cameras, and recorder equipment. This new technology requires a perioperative robotics nurse specialist who provides education for patients and family and training for members of the surgical team.

Mechanical trauma and thermal injury are two categories of injury that a patient can incur during MIS and robotic surgery (Ulmer, 2010). One limitation for both minimally invasive surgery and robotic surgery is the cost of special equipment and OR setting. In addition, surgeons require lengthy training and practice periods to become proficient in even one procedure performed using these endoscopic methods (Birch et al., 2007).

Health and Hygiene of the Surgical Team

People are a source of bacteria in the surgical setting. Everyone has bacteria on the skin and the hair and in the airways. Because these organisms can be transmitted to the patient, special health standards and dress are needed. Every surgical setting has policies and procedures for personnel and attire. Health standards require that all members of the surgical team and other support personnel in the surgical suite be free of communicable diseases. No one who has an open wound, cold, or any infection should participate in surgery.

Good personal hygiene helps prevent and control infection, as does frequent handwashing. Jewelry carries many organisms and should be minimal. All personnel must wash their hands between touching patients and performing procedures and more often when indicated. Hands of surgical personnel may be cultured on a regular basis to determine the potential for **nosocomial** (hospital-acquired) infections and to identify sources of pathogens. Further interventions or cultures are needed if quality reports (e.g., through the facility’s quality improvement program) indicate a problem. Routine cultures are usually obtained every 3 to 6 months. Surgical attire and the surgical scrub help prevent contaminations.

Surgical Attire

All members of the surgical team and all OR personnel must wear scrub attire while in the surgical suite. Scrub attire is provided by the hospital and is clean, not sterile. It is worn to reduce contamination from home and areas outside of the surgical setting. Basic surgical attire is a shirt and pants, a cap or hood (Fig. 17-6), and shoe coverings. *Staff change into clean surgical attire in the OR suite locker rooms, not at home (AORN, 2010o)*. All members of the surgical team must cover their hair, including any facial hair.

In addition to basic attire, everyone must wear protective attire. This includes a mask, eyewear, gloves, gown, and shoe covers. Everyone who enters an OR where a sterile field is present must wear a mask. Surgical team members who are

Monitor screen displaying patient's heart rate and rhythm, blood pressure, and other hemodynamic parameters

Printer to accompany the monitor

Ventilator bellows

Nitrous oxide, air, and oxygen flow meters

Anesthesia circuit

Carbon dioxide absorber

Anesthesia breathing bag

Suction canister

Pulse oximeter

Blood pressure monitor

Ventilator

Laboratory results

Vaporizers

Airway equipment (under sterile towel)

Extra supply of air (yellow) and oxygen (green)

Hazardous waste ("red bag" trash)

FIG. 17-3 **A**, A typical operating room. **B**, A typical anesthesia station with an anesthesia machine.

FIG. 17-4 How an operative laparoscope is used.

FIG. 17-5 The operating room layout for robotic surgery with the da Vinci Surgery System.

FIG. 17-6 Typical attire for all scrubbed personnel. Note complete hair covering, eye shields, mask, sterile gloves over the sleeves of the sterile gown, and shoe coverings. Note that when not in use, the hands are typically folded in front of the body, never below the waist.

scrubbed and at the patient's bedside during the surgery must also wear a sterile fluid-resistant gown, sterile gloves, and eye protectors, or face shields. Team members who are *not* scrubbed (e.g., anesthesia provider, circulating nurse) may wear cover scrub jackets that are snapped or buttoned closed (to prevent shedding of organisms from bare arms) and eyewear, as warranted.

Surgical Scrub

The surgeon, all assistants, and the scrub nurse perform a surgical scrub after putting on a mask and before putting on the sterile gown and gloves (Fig. 17-7). *The scrub does not make the hands and forearms sterile.* When the scrub is performed correctly, it reduces the number of organisms from the hands, arms, and nails. Rings, watches, and bracelets are removed before scrubbing because they may harbor organisms. Fingernails are kept short, clean, and healthy. Artificial nails are not worn because they too can harbor organisms.

A broad-spectrum, surgical antimicrobial solution is used for the surgical scrub. Plain or antimicrobial soap is used for washing hands immediately before the surgical scrub. Vigorous rubbing that creates friction is used from the fingertips to the elbow. The scrub continues for 3 to 5 minutes, followed by a rinse. During the rinse, hands and arms are positioned so that water runs off, rather than up or down, the arms (AORN, 2010p). After scrubbing, personnel enter the OR with their hands held higher than the elbows and thoroughly dry their hands and forearms with a sterile towel. This person

is then assisted into a sterile gown (“gowning”) and puts on sterile gloves (“gloving”). Newer, alcohol-based surgical scrub agents may or may not require the use of water. Operating room personnel wash and dry their hands with soap and water before applying the agent to their hands and forearms, rubbing thoroughly until dry.

Gowns, gloves, and materials used at the operative field must be sterile. These items are changed between surgical procedures and as they become contaminated. The areas of the surgical gown considered sterile are the front of the gown from the chest to the level of the sterile field. The entire sleeves of the gown are considered sterile from 2 inches above the elbow to the cuff. The back of the gown is not considered sterile because it cannot be consistently seen by the wearer. Only when they are properly scrubbed and attired do members of the surgical team handle sterile drapes and equipment.

NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

The circulating nurse sees that a sponge is dropped onto the floor from the instrument table after the first surgical incision is opened. What is this nurse's best action?

- A. Obtain an additional sterile sponge to replace the contaminated one and place it on the instrument table.
- B. Place the sponge in the circulating area to include in the final count before incision closure.
- C. Pick up the sponge and throw it out so no one slips on it.
- D. Hand the sponge back to the scrub nurse.

ANESTHESIA

The word *anesthesia* means “negative sensation.” Anesthesia delivery is a precise science. It requires the skill of an anesthesiologist, a certified registered nurse anesthetist (CRNA) working under the direction of an anesthesiologist or another physician, or an anesthesiologist assistant (AA—similar to a physician assistant) working under the direction of an anesthesiologist.

Anesthesia is an induced state of partial or total loss of sensation, occurring with or without loss of consciousness. The purpose of anesthesia is to block nerve impulse transmission, suppress reflexes, promote muscle relaxation, and, in some cases, achieve a controlled level of unconsciousness. Anesthesia providers use a separate anesthesia record for documentation.

Usually the anesthesia provider selects the type of anesthesia to be used after consulting with the patient and surgeon and after considering specific patient-related factors. The nurse and patient communicate patient preferences and fears about anesthesia to the anesthesia provider. Patient health problems are major factors in the selection and dose of anesthetic. Selection is also influenced by:

- Type and duration of the procedure
- Area of the body having surgery
- Safety issues to reduce injury, such as airway management
- Whether the procedure is an emergency
- Options for management of pain after surgery
- How long it has been since the patient ate, had any liquids, or had any drugs
- Patient position needed for the surgical procedure
- Whether the patient must be alert enough to follow instructions during surgery

FIG. 17-7 The scrubbing, gowning, and gloving process. **A**, The surgical scrub. **B**, Rinsing. Note the water falling off the hands and arms. Also note the foot-operated handle that controls the water flow. (After scrubbing and rinsing, the scrub nurse dries his hands and arms with a sterile towel inside the operating room and then is assisted into a sterile gown.) **C**, The scrub nurse prepares sterile gloves. Note that the scrub nurse's hands are *inside* the sleeve of the gown and that he is touching the sterile gloves only with the sterile sleeve. **D**, The scrub nurse puts on his first sterile glove while the sterile gown is being tied in the back. Note again that his hand never emerges from under the sterile sleeve. **E**, The scrub nurse puts on his second sterile glove.

- The patient's previous responses and reactions to anesthesia

The physical status of a patient is ranked according to a classification system developed by the American Society of Anesthesiologists (ASA). The anesthesiologist assesses the patient and assigns him or her to one of six categories based on current health and the presence of diseases and disorders. The categories rank patients in a range from a totally healthy patient (P1 ranking) to a patient who is brain dead (P6 ranking) (Johnson, 2011). This system is used to estimate potential risks during surgery and patient outcomes.

Anesthesia delivery begins with selecting and giving preoperative drugs (see Chapter 16). The nurse must know the actions of commonly used drugs and their effects during and after surgery. Anesthetic agents affect many systems and can worsen other health problems, increasing the patient's need for care. For example, most anesthetics are metabolized by the liver and excreted by the kidneys. Liver or kidney impairment increases anesthetic effects and the risk for toxicity. In addition, interactions may occur between the anesthetics and other drugs the patient has received.

Anesthesia can be induced in many ways (Table 17-1). The most common forms of anesthesia used in North America include general, regional, and local anesthesia. *Hypnosis* or *hypnoanesthesia* (which induces a passive, trance-like state),

cryothermia (use of cold [e.g., ice] to reduce the surface temperature of the surgical site), and acupuncture are used less often.

General Anesthesia

General anesthesia is a reversible loss of consciousness induced by inhibiting neuronal impulses in several areas of the central nervous system (CNS). This state can be achieved with a single agent or a combination of agents. General anesthesia depresses the CNS, resulting in **analgesia** (pain relief or pain suppression), **amnesia** (memory loss of the surgery), and unconsciousness, with loss of muscle tone and reflexes. The patient is unconscious and unaware. This type of anesthesia is used most often in surgery of the head, neck, upper torso, and abdomen. It may also be used when patients cannot cooperate.

Stages of General Anesthesia

Induction of general anesthesia involves four stages. Table 17-2 lists the expected patient responses and nursing care for each stage. The speed of **emergence** (recovery from the anesthesia) depends on the type of anesthetic agent, the length of time the patient is anesthetized, and whether a reversal agent is used. Retching, vomiting, and restlessness may occur during emergence, although not all patients have these responses.

TABLE 17-1 ADVANTAGES AND DISADVANTAGES OF VARIOUS TYPES OF ANESTHESIA

TYPE	ADVANTAGES	DISADVANTAGES
General		
Inhalation	Most controllable method Induction and reversal accomplished with pulmonary ventilation Few side effects	Must be used in combination with other agents for painful or prolonged procedures Limited muscle relaxant effects Postoperative nausea and shivering common
Intravenous	Rapid and pleasant induction Low incidence of postoperative nausea and vomiting Requires little equipment	Must be metabolized and excreted from the body for complete reversal Contraindicated in presence of liver or kidney disease Increased cardiac and respiratory depression Retained by fat cells
Balanced	Minimal disturbance to physiologic function Minimal side effects Can be used with older and high-risk patients	Drug interactions can occur Pharmacologic effects on the body may be unpredictable
Regional or Local		
	Gag and cough reflexes stay intact Allows participation and cooperation by the patient Less disruption of physical and emotional body functions Decreased chance of sensitivity to the agent Decreased intraoperative stress	Difficult to administer to an uncooperative or upset patient No way to control agent after administration Absorbs rapidly into the blood and causes cardiac depression (hypotension) or overdose Increased nervous system stimulation (overdose) Not practical for extensive procedures because of the amount of drug that would be required to maintain anesthesia
Cryothermia		
	Reflexes remain intact Decreases chance of adverse reactions Decreased intraoperative stress	No way to control depth of anesthesia Not used in long or extensive procedures May not be appropriate for an anxious patient
Hypnosis/Hypnoanesthesia		
	Reflexes remain intact	Requires patient cooperation Requires special training

TABLE 17-2 THE FOUR STAGES OF GENERAL ANESTHESIA AND RELATED NURSING INTERVENTIONS

DESCRIPTION	NURSING INTERVENTIONS	RATIONALES
Stage 1 (Analgesia and Sedation, Relaxation)		
Begins with induction and ends with loss of consciousness.	Close operating room doors, dim the lights, and control traffic in the operating room.	Avoiding external stimuli in the environment promotes relaxation.
Patient feels drowsy and dizzy, has a reduced sensation to pain, and is amnesic.	Position patient securely with safety belts.	Using safety measures in stage 1 prepares for stage 2.
Hearing is exaggerated.	Keep discussions about the patient to a minimum.	Being sensitive to the patient maintains his or her dignity.
Stage 2 (Excitement, Delirium)		
Begins with loss of consciousness and ends with relaxation, regular breathing, and loss of the eyelid reflex.	Avoid auditory and physical stimuli.	Sensory stimuli can contribute to the patient's response.
Patient may have irregular breathing, increased muscle tone, and involuntary movement of the extremities during this stage.	Protect the extremities.	Safety measures help prevent injury.
Laryngospasm or vomiting may occur.	Assist the anesthesiologist or CRNA with suctioning as needed.	Adequate suctioning of vomitus can prevent aspiration.
Patient is susceptible to external stimuli.	Stay with patient.	Staying with the patient is emotionally supportive.
Stage 3 (Operative Anesthesia, Surgical Anesthesia)		
Begins with generalized muscle relaxation and ends with loss of reflexes and depression of vital functions.	Assist the anesthesiologist or CRNA with intubation.	Providing assistance helps promote smooth intubation and prevent injury.
The jaw is relaxed, and breathing is quiet and regular.	Place patient into operative position.	Performing procedures as soon as possible promotes time management to minimize total anesthesia time for the patient.
The patient cannot hear.	Prep (scrub) the patient's skin over the operative site as directed.	
Sensations (i.e., to pain) are lost.		
Stage 4 (Danger)		
Begins with depression of vital functions and ends with respiratory failure, cardiac arrest, and possible death.	Prepare for and assist in treatment of cardiac and/or pulmonary arrest.	Teamwork and preparedness help decrease injuries and complications and promote the possibility of a desired outcome for the patient.
Respiratory muscles are paralyzed; apnea occurs.	Document occurrence in the patient's chart.	
Pupils are fixed and dilated.		

Suction equipment must be available to prevent aspiration. During recovery, shivering, rigidity, and slight cyanosis may occur. These responses are caused by a temporary change in the body's temperature control. The nurse provides warm blankets, radiant light, and oxygen to decrease the effects of emergence.

Administration of General Anesthesia

General anesthesia agents are administered by inhalation and IV injection. Table 17-3 lists common agents for general anesthesia along with their advantages and disadvantages. At times, both inhalation and IV agents are used together as “balanced anesthesia” to obtain specific effects. A combination is used to provide hypnosis, amnesia, analgesia, muscle relaxation, and reduced reflexes with minimal disturbance of physiologic function. This method provides safe and controlled anesthetic delivery, especially for older and high-risk patients. An example of balanced anesthesia is the use of thiopental for induction, nitrous oxide for amnesia, morphine for analgesia, and pancuronium for muscle relaxation. Many combinations are possible, and selection is based on the individual patient and the specific surgical procedure.

Other drugs, such as hypnotics, opioid analgesics, and neuromuscular blocking agents, may be used as part of the anesthesia regimen (see Table 17-3). Hypnotics and opioid analgesics can be used for sedation before surgery, for IV moderate sedation for short procedures, and as an adjunct to general anesthesia during surgery. The neuromuscular blocking agents are used to relax the jaw and vocal cords immediately after induction so that the endotracheal tube can be placed. These drugs also may be used during surgery to provide continued muscle relaxation.

Complications from General Anesthesia

Complications can range from minor and annoying (sore throat) to death. Improvement in anesthesia delivery and surgical techniques has resulted in a decline in anesthesia-related deaths, even among higher-risk patients. Although the anesthesia provider has the main responsibility for monitoring patient responses during surgery, the circulating nurse also remains alert for changes in the patient's condition.

Malignant hyperthermia (MH) is an acute, life-threatening complication of certain drugs used for general anesthesia. The reaction begins in skeletal muscle exposed to specific agents, causing increased calcium levels in muscle cells and increased muscle metabolism. Serum calcium and potassium levels are increased, as is the metabolic rate, leading to acidosis, cardiac dysrhythmias, and a high body temperature.

Onset of MH may occur immediately after induction of anesthesia, several hours into the procedure, or, rarely, even after the anesthetic has been terminated. Clinical features reflect the increased muscle calcium level and the greatly increased body metabolism. Manifestations include tachycardia, dysrhythmias, muscle rigidity (especially of the jaw and upper chest), hypotension, tachypnea, skin mottling, cyanosis, and **myoglobinuria** (presence of muscle proteins in the urine). *The most sensitive indication is an unexpected rise in the end-tidal carbon dioxide level with a decrease in oxygen saturation. Another early indication is sinus tachycardia. Extremely elevated temperature, as high as 111.2° F (44° C), is a late sign of MH.* Survival depends on early diagnosis and the actions of the entire surgical team. Time is crucial when

MH is diagnosed. Dantrolene sodium, a skeletal muscle relaxant, is the drug of choice along with other interventions (Kaplow, 2010).

For a known history or risk, the patient can be treated before, during, and after surgery with dantrolene to prevent this problem. Chart 17-1 lists best practices for care of the patient with MH. The AORN recommends that all operating

CHART 17-1 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Emergency Care of the Patient with Malignant Hyperthermia

- Stop all inhalation anesthetic agents and succinylcholine.
- If an endotracheal tube (ET) is not already in place, intubate immediately.
- Ventilate the patient with 100% oxygen, using the highest possible flow rate.
- Administer dantrolene sodium (Dantrium) IV at a dose of 2 to 3 mg/kg.
- Administer 100% oxygen.
- If possible, terminate surgery. If termination is not possible, continue surgery using anesthetic agents that do not trigger malignant hyperthermia (MH).
- Assess arterial blood gases (ABGs) and serum chemistries for metabolic acidosis and hyperkalemia.
- If metabolic acidosis is evident by ABG analysis, administer sodium bicarbonate IV.
- If hyperkalemia is present, administer 10 units of regular insulin in 50 mL of 50% dextrose IV.
- Use active cooling techniques:
 - Administer iced saline (0.9% NaCl) IV at a rate of 15 mL/kg every 15 minutes as needed.
 - Apply a cooling blanket over the torso.
 - Pack bags of ice around the patient's axillae, groin, neck, and head.
 - Lavage the stomach, bladder, rectum, and open body cavities with sterile iced normal saline.
- Insert a nasogastric tube and a rectal tube.
- Monitor core body temperature to assess effectiveness of interventions and to avoid hypothermia.
- Monitor cardiac rhythm by electrocardiography (ECG) to assess for dysrhythmias.
- Insert a Foley catheter to monitor urine output.
- Treat any dysrhythmias that do not resolve on correction of hyperthermia and hyperkalemia with antidysrhythmic agents *other than calcium channel blockers*.
- Administer IV fluids at a rate and volume sufficient to maintain urine output above 2 mL/kg/hr.
- Monitor urine for presence of blood or myoglobin.
- If urine output falls below 2 mL/kg/hr, consider using osmotic or loop diuretics, depending on the patient's cardiac and kidney status.
- Contact the Malignant Hyperthermia Association of the United States (MHAUS) hotline for more information regarding treatment: (800) 644-9737.
- Transfer the patient to the intensive care unit (ICU) when stable.
- Continue to monitor the patient's temperature, ECG, ABGs, electrolytes, creatine kinase, coagulation studies, and serum and urine myoglobin levels until they have remained normal for 24 hours.
- Instruct the patient and family about testing for MH risk.
- Refer the patient and family to the Malignant Hyperthermia Association of the United States at (800) 986-4287 or www.mhaus.org.
- Report the incident to the North American Malignant Hyperthermia Registry at the University of Pittsburgh: (412) 692-5464.

Data from Malignant Hyperthermia Association of the United States; and Hommertzhim, R., & Steinke, E.E. (2006). Malignant hyperthermia: The perioperative nurse's role. *AORN Journal*, 83(1), 149-164.

TABLE 17-3 ADVANTAGES AND DISADVANTAGES OF COMMON AGENTS FOR GENERAL ANESTHESIA

AGENT	ADVANTAGES	DISADVANTAGES
Inhalation Anesthetics		
Desflurane (Suprane)	Rapid induction and recovery	May increase heart rate and lower BP during induction Can induce malignant hyperthermia*
Enflurane (Ethrane)	Rapid induction and recovery Less likely to induce dysrhythmias	Respiratory depression may occur Hypotension may occur Can induce malignant hyperthermia* Lowers seizure threshold
Halothane (Fluothane)	Rapid and smooth induction Low incidence of postoperative nausea and vomiting Less irritating to the respiratory tract than other inhalation agents	Shivering common postoperatively Can induce malignant hyperthermia* Hypotension and bradycardia may occur Can increase dysrhythmias Can cause permanent liver damage (rare)
Isoflurane (Forane)	Rapid induction and recovery Induces additional muscle relaxation	Respiratory depression possible Irritating odor
Sevoflurane (Ultane)	Rapid induction and recovery Induces additional muscle relaxation	Can induce kidney impairment (rare)
Nitrous oxide (N ₂ O)	Rapid induction and recovery Useful for short procedures When used with other agents, reduces the required concentration of the other agents Minimal cardiovascular and respiratory depression	Relatively weak anesthetic agent May produce hypoxia if the concentration is high Needs addition of other agents for longer procedures
Intravenous Anesthetics		
Etomidate (Amidate)	Rapid induction and recovery Useful for short procedures Little “hang-over” effect	Can cause pain at injection site Laryngospasms (rare)
Ketamine (Ketalar)	Rapid induction and recovery Protective reflexes remain intact	Stimulates cardiovascular responses Dissociative emergence reactions Can induce nausea and vomiting
Midazolam (Versed)	Induces amnesia around the event	Slower induction than other IV agents
Propofol (Diprivan)	Rapid induction and recovery	Can cause pain at injection site May induce propofol infusion syndrome (PrIS): Severe metabolic acidosis, rhabdomyolysis, hyperkalemia, kidney injury, cardiovascular collapse
Methohexital sodium (Brevital)	Acts directly on the central nervous system	Can induce bradycardia and hypotension
Thiopental sodium (Pentothal)	Rapid induction and recovery	Can depress respiratory and cardiac functions
Neuromuscular Blockers		
Succinylcholine (SUX, Anectine)	Rapid induction and recovery	Causes fasciculations on induction Can cause malignant hyperthermia in conjunction with inhalation anesthetics*
Atracurium (Tracrium)	Rapid induction and recovery	Temporarily paralyzes muscles but does not block sensation
Cisatracurium (Nimbex)	Same as for atracurium	Same as for atracurium
Mivacurium (Mivacron)	Same as for atracurium	Same as for atracurium
Vecuronium (Norcuron)	Same as for atracurium	Same as for atracurium
Pancuronium (Pavulon)	Slower onset and longer duration than atracurium	Same as for atracurium
Opioids		
Alfentanil (Alfenta)	Rapid induction and recovery	
Fentanyl (Sublimaze)	Outstanding analgesia, anesthesia (epidural)	
Remifentanil (Ultiva)	Effective at very low doses	
Sufentanil (Sufenta)	Rapid induction and recovery	Can induce prolonged respiratory depression

*Can induce malignant hyperthermia only in susceptible people.

rooms have a dedicated MH cart containing drugs for management (normal saline, dantrolene, sodium bicarbonate, insulin, 50% dextrose, lidocaine, and calcium chloride), a protocol card listing interventions, and the MH hotline number. Additional nursing support is needed during this true perioperative emergency.

GENETIC/GENOMIC CONSIDERATIONS

MH is a genetic disorder with an autosomal dominant pattern of inheritance. The patient with a genetic predisposition for MH is at risk for this complication from halothane, enflurane, isoflurane, desflurane, sevoflurane, and succinylcholine. This rare syndrome is most common in young adults. Males are affected more often than females (despite the autosomal dominant pattern of inheritance) because of gender differences in muscle mass. Once a patient or family history of MH is known, family members can have a muscle biopsy to determine whether they are at risk. The muscle biopsy tested with the caffeine halothane contracture test (CHCT) is still considered the “gold standard” for MH testing even though this disorder is inherited. Currently, no definitive genetic test identifies all people at risk for MH. When a patient is determined to be at risk for MH, he or she can still have anesthesia and surgery; however, more precautions are needed and different anesthetic agents are used.

Overdose of anesthetic can occur if the patient’s metabolism and drug elimination are slower than expected. This is more likely to occur in patients who are older or who have liver or kidney problems. Other drugs (e.g., antihypertensives) also alter metabolism, and interactions can occur between the anesthetic and the patient’s regular drugs. Accurate information about the patient’s height, weight, and medical history, especially liver and kidney function, is vital in determining the anesthetic type and dosage. Death during surgery is more often related to pre-existing health problems than to anesthetic overdose.

Unrecognized hypoventilation occurs as an anesthesia-induced complication. Failure to exchange gases adequately can lead to cardiac arrest, permanent brain damage, and death. Monitoring standards include the use of an end-tidal carbon dioxide monitor to confirm carbon dioxide in the patient’s expired gas and a breathing system disconnect monitor to detect any break in the breathing circuit equipment.

Intubation complications can include many problems (e.g., broken or injured teeth and caps, swollen lip, vocal cord trauma). Intubation may be difficult because of anatomic variance or disease presence (e.g., small oral cavity, tight jaw joint, presence of tumor). Improper neck extension during intubation also may cause injury. The surgeon should be in the operating room (OR) during the intubation process in case a tracheostomy is needed when the endotracheal tube (ET) is placed. ET placement causes tracheal irritation and edema. Often the patient has a sore throat after surgery.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

The client undergoing induction of anesthesia with succinylcholine, a depolarizing blocker agent, begins to experience generalized muscle twitching. What is the circulating nurse’s best response?

- Call the anesthesia provider’s attention to this response.
- Ensure the client is secured to the table.
- Cover the client with a warm blanket.
- Document this expected response.

Local or Regional Anesthesia

Local or regional anesthesia briefly disrupts sensory nerve impulse transmission from a specific body area or region. Motor function may or may not be affected. The patient remains conscious and can follow instructions. Because the gag and cough reflexes remain intact, the risk for aspiration is low. Local or regional anesthesia is often supplemented with sedatives, opioid analgesics, or hypnotics to reduce anxiety and increase comfort. The OR nurse provides the patient with information, directions, and emotional support before, during, and after the procedure.

Local Anesthesia

Local anesthesia is delivered topically (applied to the skin or mucous membranes of the area to be anesthetized) and by local infiltration (injected directly *into* the tissue around an incision, wound, or lesion). Sometimes when the term *local* is used, it means *any* form of anesthesia that is not general anesthesia.

Regional Anesthesia

Regional anesthesia is a type of local anesthesia that blocks multiple peripheral nerves in a specific body region. It may be used when general anesthesia cannot be used because of medical problems, when the patient has had adverse reactions to general anesthesia, when the patient has a preference and a choice is possible, and when pain management after surgery is enhanced by regional anesthesia. If the patient has eaten and the surgery is an emergency, it may be possible to perform surgery with the patient under regional anesthesia (depending on the procedure) to decrease the risk for aspiration. Types of regional anesthesia include field block, nerve block, spinal, and epidural. [Table 17-4](#) defines the types of regional anesthesia. [Figs. 17-8 and 17-9](#) show common sites of nerve blocks, spinal anesthesia, and epidural anesthesia.

TABLE 17-4 TYPES OF REGIONAL ANESTHESIA

ANESTHESIA TYPE	DEFINITION AND COMMON USE
Field block	A series of injections <i>around</i> the operative field Most commonly used for chest procedures, hernia repair, dental surgery, and some plastic surgeries
Nerve block	Injection of the local anesthetic agent <i>into or around</i> one nerve or group of nerves in the involved area Most commonly used for limb surgery or to relieve chronic pain
Spinal anesthesia	Injection of an anesthetic agent into the cerebrospinal fluid in the subarachnoid space (see Fig. 17-9) Most commonly used for lower abdominal, pelvic, hip, and knee surgery
Epidural anesthesia	Injection of an agent into the epidural space (see Fig. 17-9) Most commonly used for anorectal, vaginal, perineal, hip, and lower extremity surgeries

FIG. 17-8 Nerve block sites.

The nurse's role in the delivery of regional anesthesia consists of:

- Assisting the anesthesia provider
- Observing for breaks in sterile technique
- Providing emotional support for the patient
- Staying with the patient
- Offering information and reassurance
- Positioning the patient comfortably and safely

Complications of Local or Regional Anesthesia

Complications of local or regional anesthesia are related to patient sensitivity to the anesthetic agent (anaphylaxis), incorrect delivery technique, systemic absorption, and overdose. The nurse observes for central nervous system (CNS) stimulation followed by CNS and cardiac depression, which are signs of a systemic toxic reaction. The nurse also assesses for restlessness, excitement, incoherent speech, headache, blurred vision, metallic taste, nausea, vomiting, tremors, seizures, and increased pulse, respirations, and blood pressure. Interventions include establishing an open airway, giving oxygen, and notifying the surgeon. Usually a fast-acting barbiturate is needed for treatment. If the toxic reaction is untreated, unconsciousness, hypotension, apnea, cardiac arrest, and death may result.

Cardiac arrest may occur as a rare complication of spinal anesthesia. Epinephrine is given to prevent cardiac arrest in patients who develop sudden, unexplained bradycardia.

Local complications include edema and inflammation as early problems. Abscess formation, tissue necrosis, and/or gangrene may occur later. Abscesses result from contamination during injection of the agent. Necrosis and gangrene are rare but may occur as a result of prolonged blood vessel constriction in the injected area.

Moderate Sedation

Moderate sedation, formerly called *conscious sedation*, is the IV delivery of sedative, hypnotic, and opioid drugs to reduce the level of consciousness but allow the patient to maintain

a patent airway and to respond to verbal commands. The amnesia action is short, and the patient usually has a rapid return to ADLs. Etomidate (Amidate), diazepam (Valium, Vivol , Novo-Dipam , midazolam (Versed), fentanyl (Sublimaze), alfentanil (Alfenta), propofol (Diprivan), and morphine sulfate are the most commonly used drugs. Moderate sedation is used for endoscopy, cardiac catheterization, closed fracture reduction, cardioversion, and other special but short procedures.

Selection of patients for moderate sedation is based on specific criteria. The physician determines whether the patient is a candidate. In most states, a credentialed registered nurse may deliver moderate sedation under physician supervision and within the state-defined scope of nursing practice. Credentialing includes advanced training in IV drug delivery, airway management, and advanced cardiac life support (ACLS).

The nurse monitors the patient during and after the procedure for response to the procedure and the drugs. The airway, level of consciousness, capnography (measure of carbon dioxide level), oxygen saturation, ECG status, and vital signs are monitored every 15 to 30 minutes until the patient is awake and oriented and vital signs have returned to baseline levels (AORN, 2010i).

Evaluation of consciousness for recovery from moderate sedation is performed using the criteria of the Ramsay Sedation Scale (RSS) (Table 17-5). This scale lists specific patient responses or behaviors to a continuum of environmental stimulation; the measures in this scale demonstrate degree of arousal from sedation without hurting the patient or unduly startling him or her.

The patient receiving IV moderate sedation can be discharged to go home with a responsible adult if capnography indicates adequate gas exchange and arousal from sedation is at an RSS 2 level. If the patient returns to the general medical-surgical nursing unit, the unit staff nurses continue monitoring. The patient is expected to be sleepy but arousable for several hours after the procedure. Oral intake is not permitted

FIG. 17-9 Administration of spinal and epidural anesthesia.

A, Spinal or epidural anesthesia is administered by inserting a spinal needle between the second and third or the third and fourth lumbar vertebrae (L2-3 or L3-4). The patient is placed in the flexed lateral (fetal) position (*shown here*) or seated on the edge of the operating bed with the back arched and the chin tucked to the chest. **B,** Spinal anesthesia (*viewed from the side*). A large needle is inserted to the surface of the dura mater, and a second, smaller needle is passed through the first to penetrate the dura mater and arachnoid mater. An anesthetic is injected, sometimes through an indwelling catheter, directly into the cerebrospinal fluid in the subarachnoid space. **C,** Epidural anesthesia (*viewed from the side*). The needle is inserted to the surface of the dura mater, and the anesthetic is injected, usually through an indwelling catheter, into the epidural space.

TABLE 17-5 RAMSAY SEDATION SCALE FOR ASSESSING POST-SEDATION CONSCIOUSNESS

RAMSAY SCORE	RESPONSE DESCRIPTORS
RSS 1	Patient is anxious and agitated or restless, or both.
RSS 2	Patient is co-operative, oriented, and tranquil (calm, not agitated).
RSS 3	Patient responds quickly, but only to commands.
RSS 4	Patient exhibits brisk response to light tapping on the forehead above the nose between the eyebrows (glabella) or a loud noise (auditory stimulus) or responds slowly to commands.
RSS 5	Patient exhibits a sluggish response to light glabellar tapping or loud auditory stimulus.
RSS 6	Patient exhibits no response to light glabellar tapping or loud auditory stimulus, which indicates he or she is not conscious. The RSS must be reapplied at intervals until full consciousness is achieved.

Data from DeJonghe, B., Cook, D., Appere-de-Vecchi, C., et al. (2000). Using and understanding sedation scoring systems: A systematic review. *Intensive Care Medicine*, 26(3), 275-285.

until 30 minutes after the patient has received the sedation or according to the physician's prescription. If the patient was intubated or had oral endoscopy, return of the gag reflex is required before resumption of oral intake. When fluids are permitted, the nurse makes sure that the patient is awake and positioned to avoid aspiration.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

History

On arrival in the surgical suite, the patient is taken to the holding area or directly into the operating suite. The holding area nurse or the circulating nurse greets the patient on arrival. As indicated in The Joint Commission's NPSGs, correct identification of the patient is the responsibility of every member of the health care team. Check the patient's identification bracelet and ask, "What is your name and when were you born?" This practice prevents errors by drowsy or confused patients. For example, if a patient is asked "Are you

! NURSING SAFETY PRIORITY

Critical Rescue

The Joint Commission's NPSGs require that you verify the patient's identity with two types of identifiers (name, medical record number, telephone number, or other person-specific identifier). Ask the patient to tell you his or her name.

Mr. Gates?” he may respond inappropriately if he is anxious or sedated. The nurse always validates identification using the medical record and identification bracelet and by asking the patient or family.

After completing the identification process, the nurse validates that the surgical consent form has been signed and witnessed. The nurse asks, “What kind of operation are you having today?” to ascertain that the patient’s perception of the procedure, the operative permit, and the operative schedule are the same. When the procedure involves a specific site, validating the side on which a procedure is to be performed (e.g., for amputation, cataract removal, hernia repair) is the responsibility of each health care professional before and at the time of surgery. The Joint Commission now recommends that the patient and the professional who knows the most about the patient (usually the surgeon performing the surgery) mark the surgical site ([The Joint Commission \[TJC\], 2010](#)). Before proceeding, each health care professional thoroughly investigates any discrepancy and notifies the surgeon and anesthesia provider. The Joint Commission (TJC) has developed a Universal Protocol for Preventing Wrong Site, Wrong Procedure, Wrong Person Surgery, and the Association of periOperative Registered Nurses has developed recommendations based on this protocol (AORN, 2010s). The nurse asks the patient about any allergies and determines whether autologous blood was donated. A special allergy bracelet on the patient’s wrist and the medical record must be verified with what has been communicated.

! NURSING SAFETY PRIORITY

Critical Rescue

If the patient’s description of the surgical site is different from that listed on the informed consent, form a time-out with the patient, yourself, and the surgeon to ascertain and mark the correct site.

The nurse checks the patient’s attire to ensure adherence with facility policy. Dentures and dental prostheses (e.g., bridges, retainers), jewelry (including body piercing), eyeglasses, contact lenses, hearing aids, wigs, and other prostheses are removed. Denture removal before anesthesia is controversial (Conlon et al., 2007). Although the denture plate could become loose and obstruct the airway during surgery, the anesthesia provider may request that dentures be left in place to ensure a snug fit of the bag-mask. In some facilities, patients may wear eyeglasses and hearing aids until after anesthesia induction.

Medical Record Review

The circulating nurse and anesthesia provider review the patient’s medical record in the holding area or the operating room (OR). The medical record provides information needed to identify patient needs during surgery and allows the circulating nurse to assess and plan specific care during and after surgery. The medical record is the main source of information on the type and location of the planned surgery. The nurse checks the medical record to ensure required data are present before surgery is started.

Advance Directives and Do-Not-Resuscitate Orders.

Ethical dilemmas may occur during or after surgery. As a patient advocate, the nurse may have to intervene on behalf of the patient’s rights and wishes. The nurse must be familiar

with the advance directives and do-not-resuscitate (DNR) orders for each patient. It is difficult for some health care providers to not treat the patient in the OR for an emergency situation, and they may ignore an advance directive or living will. Some agencies suspend DNR orders while a patient is undergoing a surgical procedure. The position statement of the Association of periOperative Registered Nurses regarding the care of patients with DNR orders states that automatically suspending a DNR or allow-natural-death order during surgery undermines a patient’s right to self-determination (AORN, 2010b).

! NURSING SAFETY PRIORITY

Action Alert

Advance directives are to be honored in the surgical environment regardless of the situation.

Allergies and Previous Reactions to Anesthesia or Transfusions. The nurse asks about allergies and previous reactions to anesthesia or blood transfusions. Allergies to iodine products or shellfish indicate a risk for a reaction to the agents used to clean the surgical area. Latex allergies are assessed with all patients. Latex-induced anaphylaxis accounts for about 10% of the anaphylactic reactions that occur during surgery (see [Chapters 19 and 22](#)). Latex-free equipment and supplies are used when there is a latex allergy. The nurse documents the allergy in the medical record and notifies the OR team.

The patient’s previous experience with anesthesia helps the nurse and anesthesia provider anticipate needs and plan interventions. For example, if a patient is restless or agitated as a reaction to anesthesia, the nurse can have padding for the siderails and protective restraints available. The use of blood and blood products during surgery may be influenced by the patient’s history, religious beliefs, preferences, and past transfusion reactions.

Autologous Blood Transfusion. Autologous blood transfusion (reinfusing the patient’s own blood) may be used for surgery. [Chapters 16 and 42](#) discuss autologous transfusion in more detail. [Chart 17-2](#) outlines best practices for autologous blood transfusion during surgery.

Laboratory and Diagnostic Test Results. The OR nurse reviews the most recent laboratory findings and test results to inform the surgical team about the patient’s health and to alert them for potential problems. These results are usually obtained within 24 to 48 hours before surgery for hospitalized patients and within 4 weeks for ambulatory surgery patients. The nurse reports all abnormal findings or results to the surgeon and anesthesia provider. Laboratory values

CHART 17-2 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Intraoperative Autologous Blood Salvage and Transfusion

- Be aware of the cell-processing method to be used.
- Make sure that collection containers are labeled for the patient.
- Assist with sterile setup as necessary.
- Assist with processing and reinfusing procedures as needed.
- Document the transfusion process.
- Monitor the patient’s vital signs during the transfusion procedure.

greater than or less than the normal range are potentially life threatening for the patient having surgery (see [Chapter 16](#)). For example, if the hemoglobin level is less than 10 g/dL, oxygen transport capacity is reduced, affecting the amount and type of anesthesia used as well as the impact of blood loss during surgery.

Medical History and Physical Examination Findings. The nurse performs a final assessment for threats to patient safety. This begins with the patient's age and general physical condition. Older patients and those who are thin or overweight are at greater risk for skin injury. Assessing mental status is important because confused patients and those who are unable to either follow instructions or communicate may not be able to tell you when a problem exists. Patients who have sensory impairment of any type are at increased risk for injury. Specific drugs, such as long-term steroid use (which increases capillary fragility and thins the skin) or fluoroquinolone antibiotics (which increase the risk for tendon rupture), as well as limitations of range or motion, require modification during positioning and threaten patient safety.

The OR nurse checks that the medical history and examination findings, including usual pulse and blood pressure, are recorded. This information provides the circulating nurse, surgeon, anesthesia provider, and PACU nurse with baseline data to assess the patient's reaction to the surgery and anesthesia. Drugs taken before surgery may affect the patient's reaction to surgery and wound healing. For example, aspirin reduces platelet action, increasing clotting time and the risk for hemorrhage.

Knowing the patient's medical history and age allows the nurse to plan interventions for the care and safety of high-risk patients ([Chart 17-3](#)). The nurse carefully monitors older patients and those with cardiac disease for potential fluid overload.

After completing the medical record review, the nurse may insert an IV catheter and perform a surgical skin preparation. The circulating nurse provides emotional support and explains procedures to the patient. If the patient is in the holding area, he or she is moved to the OR after the preoperative routine is completed.

CHART 17-3 NURSING FOCUS ON THE OLDER ADULT

Intraoperative Nursing Interventions

- Allow patients to retain eyeglasses, dentures, and hearing aids until anesthesia has begun.
- Use a small pillow under the patient's head if his or her head and neck are normally bent slightly forward.
- Lift patients into position to prevent shearing forces on fragile skin.
- Position arthritic and artificial joints carefully to prevent postoperative pain and discomfort from strain on those joints.
- Pad bony prominences to prevent pressure sores.
- Provide extra padding for those patients with decreased peripheral circulation.
- Use warming devices to prevent hypothermia.
- Cover the patient's head and feet.
- Warm IV and irrigation fluids as indicated by agency policy and manufacturer's recommendations.
- Follow strict aseptic technique.
- Carefully monitor intake and output, including blood loss.

Data from Clayton, J. (2008). Special needs of older adults undergoing surgery. *AORN Journal*, 88(3), 557-570.

! NURSING SAFETY PRIORITY

Action Alert

Once the patient has been moved into the holding area or the OR, do not leave him or her alone.

? DECISION-MAKING CHALLENGE

Safety; Teamwork and Collaboration; Quality Improvement

A very anxious patient, a 48-year-old attorney, has entered the preoperative holding area about 60 minutes before her scheduled procedure. Before the OR nurse can interview her, the patient is medicated with 2 mg midazolam (Versed). The OR schedule lists that she is scheduled to have a left breast lumpectomy as treatment for breast cancer. When you ask her what procedure she is having, her response is "I am going to have a lumpectomy of the RIGHT breast." Upon further review, you determine that the surgeon wrote, "operative consent for lumpectomy of the right breast." However, when you check the informed consent, the consent states lumpectomy, left breast, and the patient signature is present, as is the witness signature.

1. How should you proceed with the discrepancies surrounding the operative procedure among the patient, operative consent, and OR schedule?
2. Can the patient sign a new consent after she has been medicated with midazolam? Why or why not?
3. How could this have happened?
4. How can this occurrence be prevented in the future?

ANALYSIS

Priority problems for patients during surgery are:

1. Potential for injury related to improper positioning
2. Potential for infection related to invasive procedures
3. Potential for hypoventilation related to anesthesia, pain, reduced respiratory effort

PLANNING AND IMPLEMENTATION

Preventing Injury

Planning: Expected Outcomes. The patient is expected to be free of injury as indicated by:

- Adequate capillary refill and peripheral pulses in all extremities
- Peripheral sensation and motor function after surgery at the same level as before surgery
- Absence of skin redness or open skin areas
- Absence of bruising

Interventions. Interventions are used to prevent injury from positioning during surgery. Because of anesthesia and the narrow OR bed, the patient's normal defense mechanisms cannot guard against nerve or joint damage and muscle stretch or strain. In addition, pressure ulcers often start to develop during surgery (Schoonhoven et al., 2002). Thus proper positioning is important. The circulating nurse pads the operating bed with foam and/or silicone gel pads and properly places the grounding pads. He or she coordinates the transfer to the operating bed and helps the patient to a comfortable position. The skin is assessed, especially of older patients, for bruising or injury, and extra padding is placed as indicated.

FIG. 17-10 Common surgical positions.

The patient is usually in a supine position after transfer to the operating bed. Anesthesia may be initiated with the patient supine, and he or she may then be repositioned for surgery (Fig. 17-10).

The circulating nurse coordinates positioning of the patient for surgery and modifies the position according to the patient's safety and special needs. The OR nurse ensures that there is an adequate number of personnel to assist in positioning the patient. Factors influencing the timing of repositioning include:

- The surgical site
- The age and size of the patient
- The anesthetic delivery technique
- Pain on movement (conscious patient)

Factors influencing the actual position include:

- The specific procedure being performed
- The surgeon's request
- The patient's age, size, and weight
- Any pulmonary, skeletal, or muscular limitations, such as arthritis, joint replacements, emphysema, or implanted devices

Chart 17-4 lists best practices to prevent complications related to prolonged immobility during surgery.

The dorsal recumbent (supine), prone, lithotomy, and lateral positions are most often used for surgery. Fig. 17-10 shows many surgical positions and the use of protective padding. When general anesthesia is used, the nurse positions the patient slowly to prevent hypotension from blood vessel dilation. Proper positioning is ensured by assessing for:

- Anatomic alignment
- Interference with circulation and breathing
- Protection of skeletal and neuromuscular structures
- Optimal exposure of the operative site and IV line
- Adequate access to the patient for the anesthesia provider
- The patient's comfort and safety
- Preservation of the patient's dignity

Care is modified to reduce the potential complications related to specific positions. For example, patients in the lithotomy position may develop leg swelling, pain in the legs or back, reduced foot pulses, or reduced sensation from compression of the peroneal nerve. The nurse ensures proper padding and position changes at regular intervals. He or she continually assesses adequacy of circulation by checking pulses and capillary refill below pressure points. Throughout the surgery, the nurse prevents obstruction of circulation, respiration, or nerve conduction caused by tight straps, poorly placed pads and pillows, or the position of the bed.

DECISION-MAKING CHALLENGE

Patient-Centered Care

The patient is a 50-year-old thin woman (115 lb) who will be placed in the prone position during surgery.

1. What general safety considerations should be taken for a patient in the prone position?
2. What areas on this patient are most likely to be injured as a result of poor positioning or inadequate padding?

CHART 17-4 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Prevention of Complications Related to Intraoperative Positioning

Prevention of Brachial Plexus Complications (Paralysis, Loss of Sensation in Arm and Shoulder)

- Pad the elbow if tucked at the side.
- Avoid excessive abduction.
- Secure the arm firmly on a padded armboard, positioned at shoulder level, and extended less than 90 degrees.

Prevention of Radial Nerve Complications (Wrist Drop)

- Support the wrist with padding.
- Be careful not to overtighten wrist straps.

Prevention of Medial or Ulnar Nerve Complications (Hand Weakness, Claw Hand)

- Place the safety strap above or below the nerve locations.

Prevention of Peroneal Nerve Complications (Foot Drop)

- Pad knees and ankles.
- Maintain minimal external rotation of the hips.
- Support the lower extremities.
- Be careful not to overtighten leg straps.

Prevention of Tibial Nerve Complications (Loss of Sensation on the Plantar Surface of the Foot)

- Place the safety strap above the ankle.
- Do not place equipment on lower extremities.
- Urge OR personnel to avoid leaning on the patient's lower extremities.

Prevention of Joint Complications (Stiffness, Pain, Inflammation, Limited Motion)

- Place a pillow or foam padding under bony prominences.
- Maintain the patient's extremities in good anatomical alignment.
- Slightly flex joints and support with pillows, trochanter rolls, or pads.

Data from Association of periOperative Registered Nurses. (2010). Recommended practices for positioning the patient in the perioperative practice setting. In *Perioperative standards and recommended practices* (pp. 327-350). Denver: Author.

Preventing Infection

Planning: Expected Outcomes. The patient is expected to have an uninfected surgical wound or wounds. Indicators include:

- Wound edges are closed and not excessively red or swollen
- Wound is free from purulent drainage
- White blood cell counts remain at expected levels after surgery
- Patient is afebrile

Interventions. Surgical wound infections interfere with the patient's recovery, delay wound healing, contribute to rising health care costs, and are a major source of nosocomial infections. The Centers for Disease Control and Prevention (CDC) defines surgical site infections as occurring 30 days post-surgery and up to 1 year for transplant surgery ([National Center for Health Statistics, 2007](#)). Aseptic technique must be strictly practiced by all OR personnel to ensure that the patient is free from infection, as required by The Joint Commission's NPSGs. The Surgical Care Improvement Project (SCIP), as described in [Table 16-1](#) of [Chapter 16](#), has

established core measures related to the prevention of surgical site infections.

Assess the risk for infection, including identifying patients with pre-existing health problems such as diabetes mellitus, immune deficiency, obesity, and kidney disease. The nurse performs the prescribed skin preparation, protects the patient's exposure to cross-contamination, keeps traffic to a minimum, and administers prescribed antimicrobial prophylaxis. Surgery places the patient at risk for wound complications (e.g., incisional tears, lacerations), infection, and loss of body fluids. Sterile surgical technique and the use of protective drapes, skin closures, and dressings reduce complications and promote wound healing. When a wound is already infected or is at high risk for infection, antibiotics may be used directly in the wound by irrigation or by placing the drug directly into the surgical site before wound closure.

Skin and tissue closures include sutures, staples, and special tape. [Fig. 17-11](#) shows commonly used wound closures. They are used to:

- Hold wound edges in place until wound healing is complete
- Occlude blood vessels, preventing hemorrhage and fluid loss
- Prevent wound contamination

Sutures are absorbable or nonabsorbable. **Absorbable sutures** are digested over time by body enzymes. **Nonabsorbable sutures** become encapsulated in the tissue during the healing process and remain in the tissue unless they are removed. Body enzymes do not affect nonabsorbable sutures. Retention (stay) sutures (see [Fig. 17-11](#)) may be used in addition to standard sutures for patients at high risk for impaired wound healing (those having major abdominal surgery, obese patients, patients with diabetes, and those taking steroids).

After the incision is closed, the surgeon may inject a local anesthetic or instill an antibiotic into the wound. A gauze or spray dressing may be applied to protect the incision from contamination. A variety of dressings may also be used to absorb drainage and support the incision. A pressure dressing may be applied to prevent bleeding. One or more drains (see [Chapter 18](#)) may be inserted to remove secretions and fluids from within tissues around the surgical area. These secretions, if not drained, slow healing and promote bacterial growth, which could result in wound infection.

After the dressing is secure, the nurse coordinates the surgical team in positioning and transferring the patient. A roller board or a lift sheet is used to move the patient from the operating bed to a stretcher or bed. Some patients are able to move themselves over to the stretcher. The circulating nurse and anesthesia provider go with the patient to the PACU and report the patient's surgical experience to the PACU nurse (see [Chapter 18](#)).

Preventing Hypoventilation

Planning: Expected Outcomes. The patient is expected to be free of damaging events related to hypoventilation as indicated by:

- Maintenance of SaO_2 , PaO_2 , and blood pH within normal limits
- Vital signs within normal limits
- Return to presurgical level of cognitive function

Interventions. The purpose of interventions is to prevent injury resulting from anesthesia (see discussion on pp.

FIG. 17-11 Common skin closures.

273-276). The nurse, surgeon, and anesthesia provider monitor the patient according to official standards. These standards, adopted by both the American Society of Anesthesiologists and the American Association of Nurse Anesthetists, include continuous monitoring of breathing, circulation, and cardiac rhythms; blood pressure and heart rate recordings every 5 minutes; and the continuous presence of an anesthesia provider during the case.

EVALUATION: OUTCOMES

The nurse evaluates the care of the patient during surgery based on the identified priority patient problems. The expected outcomes are that the patient:

- Is safely anesthetized without complications
- Does not experience any injury related to surgical positioning or equipment
- Is free of skin or tissue contamination during surgery
- Is free of skin tears, bruises, redness, abrasion, or maceration over pressure points and elsewhere
- Maintains normal body temperature

Specific indicators for these outcomes are listed for each priority patient problem under the Planning and Implementation section (see earlier).

GET READY FOR THE NCLEX® EXAMINATION!

KEY POINTS

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Ensure that all personnel entering the OR are wearing proper OR attire for their role.
- Observe for and inform OR personnel of any break in sterile field or sterile technique.
- Use two identifiers to check the identity of the patient.

- Report to the surgeon any discrepancy between what type of surgery the patient says is going to be performed and what the informed consent form indicates.
- Review preoperative checklist and informed consent forms.
- Highlight any known allergies.
- Apply grounding pads as needed.
- Complete any needed skin preparation.
- Perform an accurate “sharps” and sponge count with the scrub nurse or surgical technologist.

GET READY FOR THE NCLEX® EXAMINATION! —cont'd**Health Promotion and Maintenance**

- Apply padding to the OR bed to maintain the patient's skin integrity.
- Position the patient comfortably and safely.
- Apply warming blanket to maintain normal body temperature.

Psychosocial Integrity

- Encourage the patient to express concerns about the surgical procedure or its possible outcome.
- Communicate patient preferences or fears about anesthesia to the anesthesia provider.
- Preserve the patient's privacy and dignity by keeping body exposure to a minimum.
- Stay with the patient during induction of anesthesia.
- Communicate information about the patient's status to waiting family members.

- Ensure that the patient's wishes, as expressed in the advance directives statement, are honored in the surgical setting.

Physiological Integrity

- Ask the patient when was the last time he or she had anything to eat or drink.
- Assess the patient for tachycardia, increased end-tidal carbon dioxide level, and increased body temperature as indicators of malignant hyperthermia.
- Maintain the malignant hyperthermia cart.
- Monitor the patient's airway, level of consciousness, oxygen saturation, ECG, and vital signs during and immediately after moderate sedation.
- Assess all skin areas and document findings before transferring the patient to the postanesthesia care unit.

Key Points
Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Apply concepts of sterile technique, asepsis, and Standard Precautions during wound assessment and dressing changes.
2. Use specific agency criteria for determining readiness of the patient to be discharged from the postanesthesia care unit.
3. Examine individual patient factors for potential threats to safety, especially the risk for surgical site infection and venous thromboembolism.

Health Promotion and Maintenance

4. Evaluate patient risk for complications of wound healing.
5. Provide postoperative education for patients and family members after surgery.

Physiological Integrity

6. Perform an ongoing head-to-toe assessment of the postoperative patient.

7. Prioritize nursing interventions for the patient recovering from surgery and anesthesia during the first 24 hours.
8. Apply knowledge of pathophysiology to monitor the patient for the complications of shock, respiratory depression, or impaired wound healing after surgery.
9. Assess the patient's level of postoperative pain, and evaluate his or her responses to coordinated pain management strategies and interventions.
10. Explain the actions, dosages, side effects, and nursing implications for different types of drug therapy for pain management after surgery.
11. Evaluate surgical incisions and wounds for complications.
12. Collaborate with health care team members to perform emergency care procedures for surgical wound dehiscence or wound evisceration.

Completion of surgery and transfer of the patient to either the postanesthesia care unit (PACU), the same-day surgery (SDS) unit (ambulatory care unit), or the intensive care unit (ICU) mark the beginning of the postoperative period. Patients are discharged from these areas when they are stable and have met specific discharge criteria. Many patients can be discharged to home shortly after the surgery is completed. They are observed and monitored until discharge criteria are

met and are then discharged. Some patients move from the specialized nursing care in the PACU to a hospital inpatient floor or ICU for additional nursing care.

The postoperative period continues after the patient's condition is stabilized, as well as after the patient is discharged from the ambulatory surgery facility or hospital. The actual time spent away from home after surgery varies according to age, physical health, self-care ability, support systems, type

and length of surgical procedure, anesthesia, any complications, and community resources. The measures recommended by the Surgical Care Improvement Project (SCIP) that were initiated during the preoperative period to prevent certain surgical complications are continued or re-evaluated during the postoperative period. (See [Chapter 16](#) and [Table 16-1](#) for an explanation of these measures.)

OVERVIEW

The purpose of a **postanesthesia care unit (PACU)** (recovery room) is the ongoing evaluation and stabilization of patients to anticipate, prevent, and manage complications after surgery. The PACU is usually located close to the surgical suite for ease of access and patient transfer. The unit is usually a large and open room to provide direct observation of all patients and easy access to supplies and emergency equipment. Adults are usually separated from children. The patient area may be divided into individual cubicles. So that each patient can be observed continuously, privacy curtains or screens are closed only during bedside procedures. Each cubicle has equipment to monitor and care for the patient, such as oxygen, suction equipment, cardiac monitors, pulse oximetry, airway equipment, and emergency drugs.

After the surgery is completed, the circulating nurse and the anesthesia provider accompany the patient to the PACU. When the patient is in critical condition, transfer may be directly from the operating room (OR) to the ICU. On arrival, The Joint Commission's National Patient Safety Goals (NPSGs) require that the anesthesia provider and the circulating nurse give the PACU nurse a verbal "hand-off" report to communicate the patient's condition and care needs.

A hand-off report that meets National Patient Safety Goal 2 requires effective communication between health care professionals. It is at least a two-way verbal interaction between the health care professional giving the report and the nurse receiving it. The language used by the person or persons giving the report is clear and cannot be interpreted in more than one way. The nurse receiving the report focuses on the report and is not distracted by the environment or other responsibilities. Standardizing the information reported helps prevent omission of critical patient-centered information and helps avoid irrelevant details ([Association of peri-Operative Registered Nurses \[AORN\], 2010](#)). The receiving nurse takes the time to restate (report back) the information to verify what was said and to make certain both the reporting person and the receiving nurse have the same understanding. The receiving nurse takes the time to ask questions and the reporting professional must respond to the questions until a common understanding is established. [Chart 18-1](#) gives an example of critical information to include in a standard hand-off report.

The PACU nurse is skilled in the care of patients with multiple medical and surgical problems immediately after a surgical procedure. This area requires in-depth knowledge of anatomy and physiology, anesthetic agents, pharmacology, pain management, extubation, surgical procedures, and advanced cardiac life support (ACLS). The PACU nurse is skilled in assessment and can make quick decisions if emergencies or complications occur. The patient is monitored closely. The anesthesia provider and surgeon are consulted as needed.

CHART 18-1 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Postoperative Hand-off Report

- Type and extent of the surgical procedure
- Type of anesthesia and length of time the patient was under anesthesia
- Tolerance of anesthesia and the surgical procedure
- Allergies (especially to latex or drugs)
- Any health problems or pathologic conditions
- Oxygen saturation
- Status of vital signs
- Core body temperature
- Type and amount of IV fluids and drugs administered
- Estimated blood loss (EBL)
- Any intraoperative complications, such as a traumatic intubation
- Preoperative drugs and patient responses
- Primary language, any sensory impairments, any communication difficulties
- Anxiety level before receiving anesthesia
- Special requests that were verbalized by the patient preoperatively
- Preoperative and intraoperative respiratory function and dysfunction
- Pertinent medical history, including substance abuse
- Location and type of incisions, dressings, catheters, tubes, drains, or packing
- Intake and output, including current IV fluid administration and estimated blood loss
- Prosthetic devices
- Joint or limb immobility while in the operating room, especially in the older patient
- Other intraoperative positioning that may be relevant in the postoperative phase
- Intraoperative complications, how managed, patient responses (e.g., laboratory values)
- Any other important intraoperative occurrences

NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

The postanesthesia recovery unit nurse is receiving a hand-off report from the nurse anesthetist and the circulating nurse for an 82-year-old client who had a 2-hour open reduction of a fractured elbow. For which reported information about the client or surgery does the receiving nurse ask the reporting team for more details?

- The client is Jewish.
- The estimated blood loss is 150 mL.
- The client reported an allergy to codeine.
- The total intraoperative urine output is 25 mL.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

History

Use the surgical team's report to plan the care for an individual patient. After receiving the report and assessing the patient, review the medical record for information about the patient's history, presurgical physical condition, and emotional status. If the patient remains as an inpatient, the surgical and anesthesia information is incorporated into the postoperative plan of care. [Chapter 16](#) identifies situations that increase a patient's risk for the potential complications listed in [Table 18-1](#).

TABLE 18-1 GENERAL POTENTIAL COMPLICATIONS OF SURGERY

Respiratory System Complications

- Atelectasis
- Pneumonia
- Pulmonary embolism (PE)
- Laryngeal edema
- Ventilator dependence
- Pulmonary edema

Cardiovascular Complications

- Hypertension
- Hypotension
- Hypovolemic shock
- Dysrhythmias
- Venous thromboembolism (VTE), especially deep vein thrombosis (DVT)
- Heart failure
- Sepsis
- Disseminated intravascular coagulation (DIC)
- Anemia
- Anaphylaxis

Skin Complications

- Pressure ulcers
- Wound infection
- Wound dehiscence
- Wound evisceration
- Skin rashes or contact allergies

Gastrointestinal Complications

- Paralytic ileus
- Gastrointestinal ulcers and bleeding

Neuromuscular Complications

- Hypothermia
- Hyperthermia
- Nerve damage and paralysis
- Joint contractures

Kidney/Urinary Complications

- Urinary tract infection
- Acute urinary retention
- Electrolyte imbalances
- Acute kidney injury (AKI)
- Stone formation

Physical Assessment/Clinical Manifestations

Assess the patient, and record data on a PACU flow chart record (Fig. 18-1). Assessment data include level of consciousness, temperature, pulse, respiration, oxygen saturation, and blood pressure. Examine the surgical area for bleeding. Monitor vital signs as often as your facility's policy states, the patient's condition warrants, and the surgeon prescribes. Once the patient is discharged from the PACU, vital signs are often measured every 15 minutes for four times, every 30 minutes for four times, every hour for four times, and then every 4 hours for 24 to 48 hours if the patient's condition is stable. Thereafter, if the patient is admitted, vital signs are assessed according to the facility's policy, the patient's condition, and the nurse's judgment.

The health care team determines the patient's readiness for discharge from the PACU by the presence of a recovery score rating of 9 to 10 on the recovery scale (see Fig. 18-1). Other criteria for discharge (e.g., stable vital signs; normal body

! NURSING SAFETY PRIORITY

Action Alert

Respiratory assessment is the most critical assessment to perform after surgery for any patient who has undergone general anesthesia, moderate sedation, or has received sedative or opioid drugs.

temperature; no overt bleeding; return of gag, cough, and swallow reflexes; the ability to take liquids; and adequate urine output) may be specific to the facility. After you determine that all criteria have been met, the patient is discharged by the anesthesia provider to the hospital unit or to home. If an anesthesia provider has not been involved, which may be the case with local anesthesia or moderate sedation, the surgeon or nurse discharges the patient once the discharge criteria have been met.

Assessment continues from the PACU to the intensive care or medical-surgical nursing unit. If the patient is to be discharged from the PACU to home, assessment is continued by home care nurses or by the patient or family members after health teaching. When the patient is transferred to an inpatient unit, complete an initial assessment on arrival (Chart 18-2).

During the postoperative period, all patients remain at risk for pneumonia, shock, cardiac arrest, respiratory arrest, venous thromboembolism (VTE), and GI bleeding. These serious complications can be prevented or the consequences reduced with coordinated care. Nursing observations and interventions are part of critical rescue management for patient safety and quality care, as defined by The Joint Commission's NPSGs, to reduce the risk for an adverse patient outcome after surgery.

Respiratory System. When the patient is admitted to the PACU, immediately assess for a patent airway and adequate gas exchange. Although some patients may be awake and able to speak, talking is not a good indicator of adequate gas exchange. An artificial airway, such as an endotracheal tube (ET), a nasal trumpet, or an oral airway, may be in place. If the patient is receiving oxygen, document the type of delivery device and the concentration or liter flow of the oxygen. Continuously monitor pulse oximetry for oxygen saturation (SpO₂) while the patient is in the PACU. The SpO₂ should be above 95% (or at the patient's presurgery baseline).

! NURSING SAFETY PRIORITY

Critical Rescue

If the oxygen saturation drops below 95% (or the patient's presurgery baseline), notify the surgeon or anesthesia provider. If it drops by 10 percentage points and you are certain it is an accurate measure, call the Rapid Response Team.

Assess the rate, pattern, and depth of breathing to determine adequacy of gas exchange. A respiratory rate of less than 10 breaths per minute may indicate anesthetic- or opioid analgesic-induced respiratory depression. Rapid, shallow respirations may signal shock, cardiac problems, increased metabolic rate, or pain.

Listen to the lungs over all lung fields to assess breath sounds. Also check symmetry of breath sounds and chest wall movement. If, for example, the patient has an ET tube, it could move down into the right mainstem bronchus and prevent left lung expansion. In this case, lung sounds on the

CHART 18-2 FOCUSED ASSESSMENT

The Patient on Arrival at the Medical-Surgical Unit After Discharge from the Postanesthesia Care Unit**Airway**

- Is it patent?
- Is the neck in proper alignment?

Breathing

- What is the quality and pattern of the breathing?
- What is the respiratory rate and depth?
- Is the patient receiving oxygen? At what setting? What is the pulse oximetry result?

Mental Status

- Is the patient awake, able to be aroused, oriented, and aware?
- Does the patient respond to verbal stimuli?

Surgical Incision Site

- How is it dressed?
- Review the amount of drainage on the dressing immediately.
- Is there any bleeding or drainage under the patient?
- Are any drains present?
- Are the drains set properly (e.g., compressed if they should be compressed, not kinked, patient not lying on them)?
- How much drainage is present in the drainage container?

Temperature, Pulse, and Blood Pressure

- Are these values within the patient's baseline range?
- Are these values significantly different from when the patient was in the postanesthesia care unit (PACU)?

Intravenous Fluids

- What type of solution is infusing and with what additives?
- How much solution was remaining on arrival?
- How much solution infused in the transport time from PACU?
- At what rate is the infusion supposed to be set? Is it?

Other Tubes

- Is there a nasogastric or intestinal tube?
- What is the color, consistency, and amount of drainage?
- Is suction applied to the tube if ordered? Is the suction setting correct?
- Is there a Foley catheter?
- Is the Foley draining properly?
- What is the color, clarity, and volume of urine output?

exchange. Indicators of muscle weakness include the inability to maintain a head lift, weak hand grasps, and an abdominal breathing pattern.

If the patient returns to an inpatient unit, complete an initial assessment on arrival (see [Chart 18-2](#)) and then continue to assess for respiratory depression or hypoxemia. Listen to the lungs to check for effective expansion and for abnormal breath sounds. Check the lungs at least every 4 hours during the first 24 hours after surgery and then every 8 hours, or more often, as indicated. Older patients, smokers, and patients with a history of lung disease are at greater risk for respiratory complications after surgery and need more frequent assessment (Sullivan, 2011). Obese patients are also at high risk for respiratory complications.

Cardiovascular System. *Vital signs* and heart sounds are assessed on admission to the PACU and then at least every 15 minutes until the patient's condition is stable. Automated

blood pressure cuffs and cardiac monitoring assist in continuous assessment.

Review vital signs after surgery for trends, and compare them with those taken before surgery. Report blood pressure changes that are 25% higher or lower than values obtained before surgery (or a 15- to 20-point difference, systolic or diastolic) to the anesthesia provider or the surgeon. Decreased blood pressure and pulse pressure and abnormal heart sounds indicate possible cardiac depression, fluid volume deficit, shock, hemorrhage, or the effects of drugs (see [Chapters 13 and 39](#)). Bradycardia could indicate an anesthesia effect or hypothermia. Older patients are at risk for hypothermia because of age-related changes in the hypothalamus (the temperature regulation center), low levels of body fat, and coolness of the OR suite (Touhy & Jett, 2010). An increased pulse rate could indicate hemorrhage, shock, or pain.

Cardiac monitoring is maintained until the patient is discharged from the PACU. For patients at risk for dysrhythmias, monitoring may continue either on telemetry units or on general medical-surgical units. In assessing the vital signs of a patient who is not being monitored continuously, compare the rate, rhythm, and quality of the apical pulse with the rate, rhythm, and quality of a peripheral pulse, such as the radial pulse. A **pulse deficit** (a difference between the apical and peripheral pulses) could indicate a dysrhythmia.

Peripheral vascular assessment needs to be performed because anesthesia and positioning during surgery (e.g., the lithotomy position for genitourinary procedures) may impair the peripheral circulation and contribute to venous thromboembolism (VTE), especially deep vein thrombosis (DVT) (Owens, 2008). Compare distal pulses on both feet for the quality of pulsation, observe the color and temperature of extremities, evaluate sensation, and determine the speed of capillary refill. Palpable pedal pulses indicate adequate circulation and perfusion of the legs.

In adherence to The Joint Commission's Surgical Care Improvement Project's (SCIP) core measures for prevention of VTE, continue the prophylactic measures initiated before surgery. Although these measures vary in type (e.g., drug therapy with anticoagulants or antiplatelet drugs, sequential compression devices, antiembolic stockings or elastic wraps, early ambulation) depending on the patient's specific risk factors and the type and extent of surgery, any preventive strategies started before surgery are usually needed for at least the first 24 hours after surgery. Reassessment of the patient's risk for VTE and the effectiveness of the preventive strategies is performed daily. Assess the feet and legs for redness, pain, warmth, and swelling, which may occur with DVT. Foot and leg assessment may be performed once during a nursing shift, once daily, or once per visit, depending on the patient's risk for complications and the facility's or agency's policy. (See [Chapters 16 and 38](#) for more information on VTE.)

Neurologic System. *Cerebral functioning* and the level of consciousness or awareness must be assessed in *all* patients who have received general anesthesia ([Table 18-2](#)) or any type of sedation. Observe for lethargy, restlessness, or irritability, and test coherence and orientation. Determine awareness by observing responses to calling the patient's name, touching the patient, and giving simple commands such as "Open your eyes" and "Take a deep breath." Eye opening in response to a command indicates wakefulness or arousability but not necessarily awareness. Determine the degree of orientation to

TABLE 18-2 IMMEDIATE POSTOPERATIVE NEUROLOGIC ASSESSMENT: RETURN TO PREOPERATIVE LEVEL

Order of Return to Consciousness After General Anesthesia

1. Muscular irritability
2. Restlessness and delirium
3. Recognition of pain
4. Ability to reason and control behavior

Order of Return of Motor and Sensory Functioning After Local or Regional Anesthesia

1. Sense of touch
2. Sense of pain
3. Sense of warmth
4. Sense of cold
5. Ability to move

person, place, and time by asking the conscious patient to answer questions such as “What is your name?” (person), “Where are you?” (place), and “What day is it?” (time).

CONSIDERATIONS FOR OLDER ADULTS

For an older adult, a rapid return to his or her level of orientation before surgery may not be realistic. Preoperative drugs and anesthetics often delay the older patient’s return of orientation (see [Chapters 16 and 17](#)).

Compare the patient’s baseline neurologic status (obtained before surgery) with the findings after surgery. Patients who had altered cerebral functioning before surgery because of another condition usually continue to have that alteration after surgery. After the patient is alert (and all other criteria have been met), he or she is discharged from the PACU. On the medical-surgical nursing unit, assess the level of consciousness every 4 to 8 hours or as indicated by the patient’s condition and the facility’s policy.

Motor function and sensory function are assessed for all patients who received general or regional anesthesia. General anesthesia depresses all voluntary motor function. Regional anesthesia alters the motor and sensory function of only part of the body. (See [Chapter 17](#) for more information on anesthesia.) *Motor and sensory assessment are very important after epidural or spinal anesthesia.* Evaluate motor function by asking the patient to move each extremity. The patient who had epidural or spinal anesthesia remains in the PACU until sensory function (feeling) and voluntary motor movement of the legs have returned (see [Table 18-2](#)). Also assess the strength of each limb, and compare the results on both sides.

Test for the return of sympathetic nervous system tone by gradually elevating the patient’s head and monitoring for hypotension. Begin this evaluation after the patient’s sensation has returned to at least the spinal dermatome level of T10. (See [Chapter 43](#) for further neurologic assessment.) After the patient is transferred to the nursing unit, continue neurologic assessment as indicated.

Fluid, Electrolyte, and Acid-Base Balance. Fasting before and during surgery, the loss of fluid during the procedure, and the type and amount of blood or fluid given affect the patient’s fluid and electrolyte balance after surgery. Fluid volume deficit or fluid volume overload may occur after

surgery. Sodium, potassium, chloride, and calcium imbalances also may result, as may changes in other electrolyte levels. Fluid and electrolyte imbalances occur more often in older or debilitated patients and in those with health problems such as diabetes mellitus, Crohn’s disease, or heart failure.

Intake and output measurement is part of the operative record and is reported by the circulating nurse to the PACU nurse. Record any intake or output, including IV fluid intake, vomitus, urine, wound drainage, and nasogastric (NG) tube drainage. You must know the total intake and output from both the OR and the PACU to assess fluid balance accurately and to complete the 24-hour intake and output record.

Hydration status is assessed in the PACU and the medical-surgical unit. To determine hydration status, inspect the color and moisture of mucous membranes; the turgor, texture, and “tenting” of the skin (test over the sternum or forehead of an older patient); the amount of drainage on dressings; and the presence of axillary sweat. Measure and compare total output (e.g., NG tube drainage, urine output, wound drainage) with total intake to identify a possible fluid imbalance. Consider insensible fluid loss, such as sweat, when reviewing total output. Continue to assess intake and output as long as the patient is at risk for fluid imbalances. Some facilities require intake and output to be measured if the patient receives IV fluids or has a catheter, drains, or an NG tube. In addition, patients who have heart disease or kidney disease may need a longer period of intake and output measurement.

IV fluids are closely monitored to promote fluid and electrolyte balance. Isotonic solutions such as lactated Ringer’s (LR), 0.9% sodium chloride (normal saline), and 5% dextrose with lactated Ringer’s (D₅/LR) are used for IV fluid replacement in the PACU. After the patient returns to the medical-surgical unit, the type and rate of IV infusions are based on need. A typical IV solution for the patient being admitted to the nursing unit is 5% dextrose with 0.45% normal saline (D₅ 0.45% NS). (See [Chapters 13 and 15](#) for further discussion of IV fluids, electrolyte balance, and hydration assessment.)

Acid-base balance is affected by the patient’s respiratory status before and during surgery; metabolic changes during surgery; and losses of acids or bases in drainage. For example, NG tube drainage or vomitus causes a loss of hydrochloric acid and leads to metabolic alkalosis. Examine arterial blood gas (ABG) values and other laboratory values. (See [Chapter 14](#) for more detailed information on acid-base imbalances.)

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

A postoperative client’s arterial blood gas (ABG) values are pH 7.36, HCO₃⁻ 21 mEq/L, PaCO₂ 35 mm Hg, PaO₂ 98 mm Hg. What is the nurse’s priority action?

- A. Compare these values with the client’s preoperative ABG values.
- B. Assess the airway and notify the physician.
- C. Document the values as the only action.
- D. Increase the oxygen flow rate.

Kidney/Urinary System. Control of urination may return immediately after surgery or may not return for hours after general or regional anesthesia. The effects of preoperative drugs (especially atropine), anesthetic agents, or manipulation during surgery can cause urine retention. Assess for

urine retention by inspection, palpation, and percussion of the lower abdomen for bladder distention or by the use of a bladder scanner (see [Chapter 68](#)). Assessment may be difficult to perform after lower abdominal surgery. Urine retention is common early after surgery and requires intervention, such as intermittent (straight) catheterization, to empty the bladder.

When the patient has an indwelling urinary (Foley) catheter, assess the urine for color, clarity, and amount. If the patient is voiding, assess the frequency, amount per void, and any symptoms. Urine output should be close to the total intake for a 24-hour period. Consider other sources of output, such as sweat, vomitus, or diarrhea stools. Report a urine output of less than 30 mL/hr (240 mL per 8-hour nursing shift) to the physician. Decreased urine output may indicate hypovolemia or renal complications. (See [Chapter 68](#) for kidney/urinary assessment.)

Gastrointestinal System. *Postoperative nausea and vomiting (PONV)* are among the most common reactions after surgery. About 30% of patients who receive general anesthesia have some form of GI upset within the first 24 hours after surgery; however, some patients are more at risk than others (Bopp et al., 2010; [Fetzer, 2008](#)). Patients with a history of motion sickness are more likely to develop nausea and vomiting after surgery. Obese patients may be at risk because many anesthetics are retained by fat cells and remain in the body longer. Abdominal surgery and the use of opioid analgesics reduce intestinal peristalsis after surgery. These problems increase the risk for prolonged nausea and vomiting after surgery. Preventive drug therapy is effective in reducing the incidence. Drugs often used are ondansetron (Zofran), a serotonin antagonist, and meclizine (Antivert, Dramamine), a sedating H1 histamine antagonist (Bopp et al., 2010).

PONV can stress and irritate abdominal and GI wounds, increase intracranial pressure in patients who had head and neck surgery, elevate intraocular pressure in patients who had eye surgery, and increase the risk for aspiration. Assess the patient continuously for PONV. Often patients have nausea as the head of the bed is raised early after surgery. This symptom may occur with or without dizziness. You can help reduce this distressing symptom by having the patient in a side-lying position before raising the head slowly.

Intestinal peristalsis may be delayed because of prolonged anesthesia time, the amount of bowel handling during surgery, and opioid analgesic use. In the PACU and later on the medical-surgical unit, assess for the return of peristalsis. *Patients who are recovering from abdominal surgery often have decreased or no peristalsis for at least 24 hours.* This problem may persist for several days for those who have GI surgery.

Listen for bowel sounds in all four abdominal quadrants and at the umbilicus. If NG suction is being used, turn off the suction before listening to prevent mistaking the sound of the suction for bowel sounds. *The presence of active bowel sounds usually indicates return of peristalsis; however, the absence of bowel sounds does not confirm a lack of peristalsis. The best indicator of intestinal activity is the passage of flatus or stool.* Abdominal cramping along with distention denotes trapped, nonmoving gas—not peristalsis.

Decreased peristalsis occurs in patients who have a paralytic ileus. The abdominal wall is distended, and there is no movement of the intestinal wall. Assess for the manifestations of paralytic ileus (few or absent bowel sounds, a distended

TABLE 18-3 CALCULATING NASOGASTRIC TUBE DRAINAGE

Formula

Drainage in collection device – Amount of irrigant = True (actual) amount of drainage

Example

A patient's drainage container was marked at 150 mL at 7 AM. At 3 PM, there was 525 mL in the container. During the nursing shift, the nurse instilled 30 mL of saline as an irrigant into the tube four times, as prescribed by the physician.

525 mL – 150 mL = 375 mL of drainage

30 mL × 4 = 120 mL of irrigant

375 mL – 120 mL = 255 mL of actual drainage

abdomen, abdominal discomfort, vomiting, no passage of flatus or stool).

A nasogastric (NG) tube may be inserted during surgery to decompress and drain the stomach, to promote GI rest, and to allow the lower GI tract to heal. It may also be used to monitor any gastric bleeding and to prevent intestinal obstruction. One of the most common tubes used is the Salem sump. The Salem sump is a double-lumen tube with an air vent to keep the tube from grabbing the gastric mucosa. This feature allows easy drainage of the stomach and prevents mucosal damage. Less commonly used is the Levin tube, which is a single-lumen tube with no air vent. To promote drainage, suction (usually low) is applied to the NG tube. Suction is either continuous (recommended for the Salem sump) or intermittent.

Record the color, consistency, and amount of the NG drainage every 8 hours ([Table 18-3](#)). In some instances, an occult blood test (Gastrocull) may be performed. Normal NG drainage fluid is greenish yellow. Red drainage fluid indicates active bleeding, and brown liquid or drainage with a “coffee-ground” appearance indicates old bleeding. Assess that the NG tube is securely taped to the nose, and note any skin irritation.

Assess the patient for complications related to NG tube use, such as fluid and electrolyte imbalances, aspiration, and nares discomfort. To prevent aspiration, check the tube placement every 4 to 8 hours and before instilling any liquid into the tube. (See [Chapter 58](#) for information on tube placement and care.) Fluid and electrolyte imbalances can result from NG drainage and tube irrigation with water instead of saline. Imbalances include fluid volume deficit, hypokalemia and hyponatremia (see [Chapter 13](#)), hypochloremia, and metabolic alkalosis (see [Chapter 14](#)).

! NURSING SAFETY PRIORITY

Action Alert

After gastric surgery, do not move or irrigate the NG tube unless prescribed by the surgeon.

Constipation may occur after surgery as a result of anesthesia, analgesia (especially opioid analgesics), decreased activity, and decreased oral intake. Assess the abdomen by inspection, auscultation, palpation, and percussion and record the elimination pattern to determine whether interventions are needed. For abdominal assessment, auscultate

before palpation or percussion because these two maneuvers can affect peristalsis. Increased dietary fiber intake, the use of mild laxatives or bulk-forming agents, or the use of enemas may be needed.

Skin Assessment. The clean surgical wound heals at skin level in about 2 weeks in the absence of trauma, connective tissue disease, malnutrition, or the use of some drugs, such as steroids. Smokers and patients who are older, obese, or diabetic or whose immunity is reduced have delayed wound healing. Complete healing of all tissue layers within the surgical wound may take 6 months to 2 years. The physical health and age of the patient, size and location of the wound, and stress on the wound all affect healing time. Head and facial wounds heal more quickly than abdominal and leg wounds because of the better blood flow to the head and neck.

Normal Wound Healing. During the first few days of normal wound healing, the incised tissue regains blood supply and begins to bind together. Fibrin and a thin layer of epithelial cells seal the incision. After 1 to 4 days, epithelial cells continue growing in the fibrin and strands of collagen begin to fill in the wound gaps. This process continues for 2 to 3 weeks. *At that time, the wound appears to be healed; however, healing is not complete for up to 2 years, until the scar is strengthened* (McEwen, 2007). (See Chapter 26 for discussion of wound healing and wound infection.)

When the patient is an inpatient, the surgeon usually removes the original dressing on the first or second day after surgery. Assess the incision on a regular basis, at least every 8 hours, for redness, increased warmth, swelling, tenderness or pain, and the type and amount of drainage. Some drainage, changing from **sanguineous** (bloody) to **serosanguineous** to **serous** (serum-like, or yellow), is normal during the first few days. Serosanguineous drainage continuing beyond the fifth day after surgery or increasing in amount instead of decreasing alerts you to the possibility of dehiscence (discussed below), and the surgeon should be notified. Crusting on the incision line is normal, as is a pink color to the line itself, which is caused by inflammation from the surgical procedure. Slight swelling under the sutures or staples is also normal. Redness or swelling of or around the incision line, excessive tenderness or pain on palpation, and purulent or odorous drainage indicate wound infection and must be reported to the surgeon.

Impaired Wound Healing. Impaired wound healing may be caused by infection, distention from edema or paralytic ileus, stress at the surgical site, and health problems that cause delayed wound healing (e.g., diabetes). Wound **dehiscence** is a partial or complete separation of the outer wound layers, sometimes described as a “splitting open of the wound.” **Evisceration** is the total separation of all wound layers and protrusion of internal organs through the open wound (Fig. 18-2). Both of these problems occur most often between the fifth and tenth days after surgery (Beattie, 2007). Wound separation occurs more often in obese patients and those with diabetes, immune deficiency, or malnutrition or who are using steroids (Baugh et al., 2007). Dehiscence or evisceration may follow forceful coughing, vomiting, or straining and when not splinting the surgical site during movement. The patient may state, “Something gave way” or “I feel as if I just split open.”

Dressings and Drains. Assess all dressings, including casts and elastic (Ace) bandages, for bleeding or other drainage

FIG. 18-2 Complications of wound healing.

on admission to the PACU and then hourly thereafter. When the patient is on the nursing unit, assess the dressing each time vital signs are taken (at least every 8 hours). During dressing inspection, check for drainage and record its amount, color, consistency, and odor. If drainage is present on a dressing or cast, monitor its progression by outlining it with a pencil and indicating the date and time. Check the area underneath the patient also, because drainage or blood may leak from the side of the dressing and not appear on the dressing itself.

Ensure that the dressing does not restrict circulation or sensation. This problem is most likely to occur when dressings are tight or completely encircle an arm or a leg. Chest dressings that are too tight or that encircle the chest can restrict breathing.

The surgeon inserts a drain into or close to the wound if more than a minimal amount of drainage is expected. A Penrose drain (a single-lumen, soft, open, latex tube) is a gravity-type drain under the dressing. Drainage on the dressing is expected with open tube drains but is not expected with closed drainage systems. Assess closed-suction drains, such as Hemovac, Vacu-Drain, and Jackson-Pratt drains, for maintenance of suction. Specialty drains, such as a T-tube, may be placed for specific drainage purposes. For example, a T-tube drains bile after a cholecystectomy. Chronic wounds or wounds that heal by delayed primary intention are drained with a negative pressure wound device. Fig. 18-3 shows commonly used drains.

Assess all drains for patency when the patient is admitted to the PACU and every time vital signs are taken. Monitor the amount, color, and type of drainage while the patient is in the PACU and at least every 8 hours after he or she is transferred to the medical-surgical nursing unit. Large amounts of sanguineous drainage may indicate internal bleeding.

Discomfort/Pain Assessment. The patient almost always has pain or discomfort after surgery. Pain is a subjective experience and may be more intense than the health care professional can appreciate. Pain after surgery is related to the surgical wound, tissue manipulation, drains, positioning during surgery, presence of an endotracheal (ET) tube, and the patient's experience with pain. In assessing his or her discomfort and need for medication, consider the type,

FIG. 18-3 Types of surgical drains. Gravity drains, such as the Penrose (**A**) and the T-tube (**B**) drain directly through a tube from the surgical area. In closed wound drainage systems, such as the Jackson-Pratt (**C**) and Hemovac (**D**), drainage collects in a collecting vessel by means of compression and re-expansion of the system.

extent, and length of the surgical procedure. Assess for physical and emotional signs of acute pain, such as increased pulse and blood pressure, increased respiratory rate, profuse sweating, restlessness, confusion (in the older adult), wincing, moaning, and crying. When possible, ask the patient to rate the pain before and after drugs are given (e.g., on a scale of 0 to 10, with 0 being no pain and 10 being extreme pain). Plan the patient's activities around the timing of analgesia to improve mobility. Observe for a return of normal (baseline) physical and emotional behaviors. (See [Chapter 5](#) for further discussion of pain assessment.)

Pain assessment is started by the PACU nurse. After the patient is transferred from the PACU, the medical-surgical nurse continues to assess the patient's comfort level. Pain usually reaches its peak on the second day after surgery, when the patient is more awake and more active and the anesthetic agents and drugs given during surgery have been excreted.

Psychosocial Assessment

Consider the psychological, social, and cultural issues of the patient after surgery as you provide physical care. This assessment may be delayed or difficult to perform in the PACU when the patient is drowsy or confused. Consider the patient's age and medical history, the surgical procedure, and the

impact of surgery on recovery, body image, roles, and lifestyle.

Physical signs of anxiety include restlessness; increased pulse, blood pressure, and respiratory rate; and crying. The patient may be anxious and ask questions about the results or findings of the surgical procedure. Reassure the patient that the surgeon will speak with him or her after he or she is fully awake. If the surgeon has already spoken with the patient, reinforce what was said.

After the patient returns to the medical-surgical unit, continue the psychosocial assessment and also assess significant others for psychological discomfort.

NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

The client who had neck surgery to remove the entire thyroid gland is transferred to the medical-surgical unit after 4 hours in the PACU. The client reports difficulty swallowing. What is the nurse's priority action?

- Assess the client's respiratory status.
- Inspect the client's throat with a penlight.
- Adjust the position of the drain in the incision.
- Reassure the client that this is a normal and common problem after anesthesia.

Laboratory Assessment

Laboratory tests are performed after surgery to monitor for complications. Tests are based on the surgical procedure, the patient's medical history, and clinical manifestations after surgery. Common tests include analysis of electrolytes and a complete blood count (see [Chart 16-3](#) in [Chapter 16](#)). A change in laboratory test results (e.g., electrolyte, hematocrit, hemoglobin levels) often occurs during the first 24 to 48 hours after surgery because of blood and fluid loss and the body's reaction to the surgical process. Fluid loss with minimal blood loss may cause hemoconcentration of laboratory values. Such test results are reported as increased but actually represent a concentrated normal value.

An indication of infection is an increase in the band cells (immature neutrophils) in the white blood cell differential count. This increase is termed a “left-shift” (sometimes called *bandemia*). The source of infection may be the respiratory system, urinary tract, surgical wound, or IV site. Obtain specimens for culture and sensitivity testing, and monitor the culture reports at 24, 48, and 72 hours. Notify the surgeon of positive culture results. (See [Chapters 19 and 25](#) for information on infection and assessment of immune function.)

Arterial blood gas (ABG) tests may be needed for patients who have respiratory or cardiac disease, those undergoing mechanical ventilation after surgery, and those who had chest surgery. Review ABG results, and notify the surgeon of any acid-base imbalance or hypoxemia. (For more discussion on arterial blood gases and acidosis, see [Chapter 14](#).)

Urine and kidney laboratory tests also may be obtained (e.g., urinalysis, urine electrolyte levels, serum creatinine levels). Other laboratory tests depend on the diagnosis, type of surgical procedure, and other health problems. Examples are a serum amylase level for a patient who had pancreatic surgery and a blood glucose level for a patient with diabetes.

ANALYSIS

Priority patient problems for the patient after surgery are:

1. Potential for hypoxemia related to the effects of anesthesia, pain, opioid analgesics, and immobility
2. Potential for wound infection and delayed healing related to wound location, decreased mobility, drains and drainage, and tubes
3. Pain related to the surgical incision, positioning during surgery, and endotracheal (ET) tube irritation

PLANNING AND IMPLEMENTATION

Preventing Hypoxemia

Planning: Expected Outcomes. The patient is expected to attain or maintain optimal lung expansion and breathing patterns after surgery as indicated by:

- Partial pressure of arterial oxygen (PaO_2) within normal range
- Partial pressure of arterial carbon dioxide (PaCO_2) within normal range
- Oxygen saturation values within normal range

Interventions

Airway Maintenance. After assessing the airway, you may need to insert an oral airway if the patient does not already have one. The oral airway pulls the tongue forward and holds it down to prevent obstruction. If the patient had oral surgery or has clenched teeth, a large tongue, or upper airway

CHART 18-3 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Emergency Care of the Patient Experiencing a Benzodiazepine Overdose

- Secure the airway and IV access before starting benzodiazepine antagonist therapy.
- Prepare to administer flumazenil (Romazicon)* in a dose of 0.2 mg to 1 mg IV.
- Repeat drug every 2 to 3 minutes up to 3 mg, as needed, depending on the patient's response.
- Give oxygen if hypoxia is present or if respirations are below 10 breaths per minute.
- Have suction equipment available because flumazenil can trigger vomiting and a drowsy patient is at risk for aspiration.
- Continuously monitor vital signs and level of consciousness for reversal of overdose.
- Do not leave the patient until he or she is fully responsive.
- Continue to monitor the patient's vital signs and level of consciousness every 10 to 15 minutes for the first 2 hours because flumazenil is eliminated from the body more quickly than is the benzodiazepine.
- Determine the need for additional flumazenil therapy 1 to 2 hours after the patient initially becomes fully responsive.
- Observe the patient for tremors or convulsions because flumazenil can lower the seizure threshold in patients who have seizure disorders.
- Assess the IV site every shift because flumazenil can cause thrombophlebitis at the injection site.
- Observe the patient for side effects of flumazenil, including skin rash, hot flushes, dizziness, headache, sweating, dry mouth, and blurred vision. The incidence of these side effects increases with higher total doses of flumazenil.

*There are other benzodiazepine antagonists; however, flumazenil is used most often to manage adult benzodiazepine overdose in the postoperative period.

obstruction, insert a nasal airway (nasal trumpet) to keep the airway open. Keep the manual resuscitation bag and emergency equipment for intubation or tracheostomy nearby. For patients whose only airway is a tracheostomy or laryngectomy stoma, alert other staff members by posting signs in the room and notes on the chart.

Monitoring. Monitor oxygen saturation (SpO_2) with pulse oximetry at least every hour or more often, according to the patient's condition. Patients who normally have a low PaO_2 , such as those with lung disease or older adults, are at higher risk for hypoxemia. An older adult is often prescribed low-dose oxygen for the first 12 to 24 hours after surgery to reduce confusion from anesthesia and sedation (Sullivan, 2011). A patient who received moderate sedation with a benzodiazepine such as midazolam (Versed) or lorazepam (Ativan, Nu-Loraz ) may be overly sedated or have respiratory depression sufficient to need reversal with flumazenil (Romazicon) ([Chart 18-3](#)). Hypothermia after surgery causes shivering that increases oxygen demand and can induce hypoxemia. Many rewarming methods can be used, although prevention is more important. The highest incidence of hypoxemia after surgery occurs on the second postoperative day.

Positioning. In the PACU, immediately position the patient in a semi-Fowler's position unless contraindicated. If the patient cannot have the head of the bed raised, either place him or her in a side-lying position or turn the head to the side to prevent aspiration.

Oxygen Therapy. Hypoxemia is prevented and managed with oxygen therapy. Apply oxygen by face tent, nasal cannula,

or mask to eliminate inhaled anesthetic agents, increase oxygen levels, raise the level of consciousness, and reduce confusion. After the patient is fully reactive and stable, raise the head of the bed to promote respiratory function.

Depending on the surgeon's preference and established guidelines, oxygen therapy may continue through the second day after surgery. When hypoxemia occurs despite preventive care, interventions such as respiratory treatments and mechanical ventilation may be used to manage the cause of the hypoxemia.

Breathing Exercises. After the patient regains the gag and cough reflexes and meets the agency's criteria for extubation (if intubated), remove the airway or ET tube. Usual extubation criteria include the ability to raise and hold the head up and evidence of thoracic breathing. Help the patient cough (with the incision splinted) and deep breathe to expand the lungs, promote gas exchange, and eliminate anesthetic agents. [Chart 16-5](#) in [Chapter 16](#) reviews breathing exercises and splinting of the surgical area. As soon as the patient is awake enough to follow commands, urge him or her to cough, use the incentive spirometer, and take deep breaths. Remind him or her to continue these activities every 1 to 2 hours throughout the postoperative period. The patient who is unable to remove mucus or sputum requires oral or nasal suctioning. Perform mouth care after removing secretions.

Movement. Assist the patient out of bed and to ambulate as soon as possible to help remove secretions and promote lung expansion. Even when the patient has had extensive surgery, the expectation may be to get out of bed the day of or the first day after surgery. If this is not possible, assist him or her to turn at least every 2 hours (side to side) and ensure that breathing exercises and leg exercises are performed (see [Charts 16-5 and 16-6](#) in [Chapter 16](#)). Early ambulation reduces the risk for pulmonary complications, especially after abdominal, pelvic, or spinal surgery. In addition, it improves circulation to the extremities and reduces the risk for venous thromboembolism (VTE), especially deep vein thrombosis (DVT). The patient may report pain and resist getting up, but you should stress the importance of activity to prevent complications. When indicated, offer pain medication 30 to 45 minutes before he or she gets out of bed.

Preventing Wound Infection and Delayed Healing

Planning: Expected Outcomes. The patient is expected to have incision healing without wound complications as indicated by:

- Wound edges remaining together
- No purulent drainage, induration, or redness in, from, or around the incision

Interventions. Nursing assessment of the surgical area is critical (see the discussion of [skin assessment](#) on p. 291). Although most wound complications do not require additional surgical intervention, emergency surgical procedures may be needed.

Nonsurgical Management. Wound care includes reinforcing the dressing, changing the dressing, assessing the wound for healing and infection, and caring for drains, including emptying drainage containers/reservoirs, measuring drainage, and documenting drainage features. Emphasize the importance of early deep-breathing exercises to prevent forceful coughing. Encourage hip flexion when the patient is in the supine position to reduce tension on a chest or

CHART 18-4 NURSING FOCUS ON THE OLDER ADULT

Best Practice in Postoperative Skin Care

Improve perfusion to the wound to promote wound healing:

- Keep the patient adequately hydrated to maintain cardiac output.
- Keep the airway patent, and provide adequate oxygenation.
- Keep the patient's oxygen saturation on pulse oximetry at greater than 93%.

Conserve the patient's energy:

- Allow the patient to sleep in a darkened, quiet room.
- Administer drugs to combat pain and sleeplessness, as prescribed.
- Provide rest periods throughout the day.
- Control the patient's room temperature.
- Assist in ADLs.

Place the patient on a safety program to prevent falls, if indicated.

Use strict aseptic technique in caring for breaks in the integument (e.g., IV or other catheters, indwelling urethral catheter, wound).

Maintain the patient's psychosocial health:

- Prevent unnecessary stressors.
- Allow the patient liberal visitation of supportive others.
- Enable the patient to use individual successful coping mechanisms.
- Keep the patient well groomed and bathed.

Protect fragile skin:

- Minimize the use of tape on the skin.
- Use hypoallergenic tape or Montgomery straps.
- Change dressings as soon as they become wet.
- Lift the patient during transfer or repositioning.

Data from Jones, P.L., & Millman, A. (1990). Wound healing and the aged patient. *Nursing Clinics of North America*, 25(1), 263-277.

abdominal wound. Remind the patient to always splint the incision when coughing. Promote wound healing and protection of the skin in general, especially for the older patient ([Sullivan, 2011](#)). [Chart 18-4](#) lists best practices for skin care of the older patient after surgery.

Dressings. The surgeon usually performs the first dressing change to assess the wound, remove any packing, and advance (pull partially out) or remove drains. Before the first dressing change, reinforce the dressing (add more dressing material to the existing dressing) if it becomes wet from drainage. Document the added material, as well as the color, type, amount, and odor of drainage fluid and time of observation. Assess the surgical site at least every shift, and report any unexpected findings to the surgeon.

After removal of the dressing, the surgeon may leave the suture or staple line open to the air, which allows easy assessment of the wound and early detection of poor wound edge adherence, drainage, swelling, or redness. Some surgeons believe that air-drying promotes healing. A draining wound, however, is always covered with a dressing.

Dressing changes are prescribed by the surgeon; however, the facility or unit may have standards or policies that dictate specific protocols for dressing changes and incision care. An unchanged wet or damp dressing is a source of infection. Change dressings using aseptic technique until the sutures or staples are removed.

Dressings vary with the surgical procedure and the surgeon's preference. Common dressings for large incisions consist of gauze or nonadherent pads covered with a larger absorbent pad held in place by tape, a tubular stretchy net, or Montgomery straps ([Figs. 18-4 and 18-5](#)). Some incisions

FIG. 18-4 Montgomery straps may be used when frequent dressing changes are anticipated. They help prevent skin irritation from frequent tape removal.

FIG. 18-5 Patient with a dressing held in place with Montgomery straps.

may be covered with a transparent plastic surgical dressing (e.g., OpSite) or a spray in the operating room. This type of dressing stays intact for 3 to 6 days and allows direct observation of the wound. It also prevents contamination and eliminates the need for dressing changes.

Wound or suture line care consists of changing gauze dressings at least once during a nursing shift or daily and may include cleaning the area with sterile saline or some other solution. Some suture lines are left open to air without any dressing to cover the incision. The hospital's policy, the unit's standards, and the surgeon's preference determine what solution, if any, is used to clean the wound and how often dressings are changed (McEwen, 2007). For large dressing changes or drain removal, offer the patient a prescribed analgesic before the procedure. Always assess the skin for redness, rash, or blisters in areas where tape has been used. Tape can cause a skin reaction after surgery even among patients who are not known to be tape sensitive.

Skin sutures or staples are usually removed 5 to 10 days after surgery, although this varies up to 30 days depending on the type of surgery and the patient's health. The incision may then be secured with SteriStrips. The surgeon or the nurse removes the sutures or staples, depending on the agency's policy. Clean the incision before removing sutures or staples. Before removing sutures, examine the condition and healing stage of the wound. First remove every other suture or staple and re-assess the wound for integrity. If wound healing is progressing normally, the rest of the sutures or staples may then be removed or may be removed the next day. If the wound does not appear to be healing well, notify the surgeon before removing any sutures.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

When changing the client's abdominal dressing on the second postoperative day, the nurse observes crusting on about half of the suture line and oozing of a small amount of serosanguineous drainage. What is the nurse's best action?

- Loosen the sutures or staples in the area where crusts have formed.
- Clean the suture line with sterile saline and apply new dressings.
- Gently remove the crusts and culture the material beneath.
- Apply pressure over the incision and notify the surgeon.

Drains. Drains (see Fig. 18-3) may be placed in the wound or through a separate small incision (known as a “stab” wound) close to the incision during surgery. Drains provide an exit route for air, blood, and bile. Drains also help prevent deep infections and abscess formation during healing.

The Penrose drain is placed into the external aspect of the incision and drains directly onto the dressing and skin around the incision. Change a damp or soiled dressing, and carefully clean under and around the Penrose drain. Then place absorbent pads under and around the exposed drain to prevent skin irritation and wound contamination. Whether sutured in place or not, the drain can be dislodged or pulled out accidentally during a dressing change. It is also possible for the drain to slip back through the wound into the patient. Usually this complication is prevented when the drain is first placed in the OR. The surgeon pins a sterile safety pin through the drain at an angle perpendicular to the drain and the wound. The safety pin acts as a barrier to prevent the drain from slipping. As the wound heals, the surgeon or nurse shortens (advances) the drain by pulling it out a short distance and trimming off the excess external portion so that only 2 to 3 inches of drain protrudes through the incision. The stabilizing safety pin must be repositioned each time the drain is advanced. The drain remains in place until drainage stops.

Jackson-Pratt and Hemovac drains are two self-contained drainage systems that drain wounds directly through a tube via gravity and vacuum. These drains are sutured in place with a suture that seals the area when the drain is removed. Use sterile technique to empty the reservoir. Record the amount and color of drainage during every nursing shift or more often if prescribed. After emptying and compressing the reservoir to restore suction, secure the drain to the patient's gown (never to the sheet or mattress) to prevent pulling and stress on the surgical wound.

Drug Therapy. Wound infection is a major complication after surgery. It usually results from contamination during surgery, preoperative infection, debilitation, or immunosuppression. In accordance with the Surgical Care Improvement Project's (SCIP) core measures for prevention of surgical site infection, a patient at risk for wound infection may have received antibiotic therapy with drugs that are effective against organisms common to the specific surgical site both before and during surgery. The need for these antibiotics is re-evaluated at 24 hours after surgery. Unless manifestations of infection are present, the antibiotic is discontinued at that time (SCIP Infection-3; see Table 16-1 in Chapter 16). If manifestations of wound infection are present, these must be documented to justify continuation of antibiotic therapy.

As suggested by The Joint Commission's NPSGs, wounds that become infected and open are treated with dressing changes and systemic antibiotic therapy. Depending on the surgeon's prescription, irrigate the wound (e.g., with sterile saline, hydrogen peroxide, povidone-iodine, or acetic acid), loosely pack it with solution-soaked gauze (e.g., neomycin, gentamicin, iodoform, povidone-iodine, saline, or acetic acid), and cover the wound with dry, sterile dressings. This procedure (wet-to-damp dressings) may be done one to three times daily. The packing promotes healing from within the wound and **débridement** (removal of the infected or dead tissue) as the wound heals.

Surgical Management. Poorly healing wounds, infected wounds, or complicated wounds may require surgical intervention.

Management of Dehiscence. If dehiscence (wound opening) occurs, apply a sterile nonadherent (e.g., Telfa) or saline dressing to the wound and notify the surgeon (Beattie, 2007). Instruct the patient to bend the knees and to avoid coughing. A wound that becomes infected dehisces by itself, or it may be opened by the surgeon through an incision and drainage (I&D) procedure. In either case, the wound is left open rather than re-sutured and is treated as described previously.

Management of Evisceration. An **evisceration** (a wound opening with protrusion of internal organs) is a surgical emergency (Beattie, 2007). Chart 18-5 lists best practices for emergency care of the patient with surgical wound evisceration. Provide emotional support by explaining what happened and reassuring the patient that the emergency will be handled competently.

! NURSING SAFETY PRIORITY

Critical Rescue

When a surgical wound evisceration occurs, one nurse tends to the patient while another nurse immediately notifies the surgeon.

The surgeon may prescribe a nasogastric (NG) tube to decompress the stomach and relieve internal pressure or to remove the stomach's contents if the patient has been eating and general anesthesia is needed. Prepare the patient for surgery (see Chapter 16) to close the wound. Regional or local anesthesia may be used, depending on the location and type of wound. Nausea and vomiting, which stress the already fragile incision, are reduced when regional or local anesthesia is used. To increase the incision's integrity, stay or retention sutures of wire or nylon are used along with standard sutures or staples (see Fig. 17-11 in Chapter 17).

CHART 18-5 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Emergency Care of the Patient with Surgical Wound Evisceration

1. Call for help! Instruct the person who responds to notify the surgeon or Rapid Response Team immediately and to bring any needed supplies into the patient's room.
2. Stay with the patient.
3. Cover the wound with a nonadherent dressing premoistened with warmed sterile normal saline. **NOTE:** The supplies needed for this emergency should be in the patient's room, especially if the patient is at high risk.
4. If premoistened dressings are not available, moisten sterile gauze or sterile towels in a sterile irrigation tray with sterile saline and then cover the wound.
5. If saline is not immediately available, cover the wound with gauze and then moisten with sterile saline using a sterile irrigation tray as soon as someone brings saline.
6. Do not attempt to reinsert the protruding organ or viscera.
7. While covering the wound, note the patient's response and assess for manifestations of shock.
8. Place the patient in a supine position with the hips and knees bent.
9. Raise the head of the bed 15 to 20 degrees.
10. Take vital signs, and document them. **NOTE:** If the person who answered the call for help is back in the room before this, instruct him or her to take vital signs while you focus on covering the wound and repositioning the patient.
11. Provide support and reassurance to the patient.
12. Continue assessing the patient, including vital signs assessment, every 5 to 10 minutes until the surgeon arrives.
13. Keep dressings continuously moist by adding warmed sterile saline to the dressing as often as necessary. Do not let the dressing become dry.
14. When the surgeon arrives, report your finding and your interventions. Then follow the surgeon's directions.
15. Document the incident, the activity the patient was engaged in at the time of the incident, your actions, and your assessments.

Prevention. Patients also are at risk for developing pressure ulcers from positioning during surgery, prolonged contact with damp surgical linens, and contact with unpadding surfaces. Pressure ulcers acquired during the surgical period increase lengths of stay and the risk for complications. Addressing early-stage pressure ulcers can prevent progression and limit complications.

? DECISION-MAKING CHALLENGE

Patient-Centered Care

A 55-year-old female patient with a history of smoking and obesity is returned to the surgical unit after a 3-hour abdominal procedure. She has a nasogastric tube with orders for intermittent suction, a Foley catheter draining clear amber urine, an IV of 0.9% saline at 100 mL/hr, and an abdominal dressing that is dry and intact. Her vital signs are as follows: HR = 65 beats/min; BP = 138/80 mm Hg; R = 20; and T = 98.9° F. After the patient has been moved to the bed, she reports dull pain in her right calf. She is wearing thigh-high antiembolism stockings.

1. What additional assessment data should you obtain?
2. Should the surgeon be notified? Why or why not?
3. If the physician diagnoses the patient with possible deep vein thrombosis, which tests and treatments should you anticipate for this patient?

Examine the patient's skin for areas of redness or open areas. Document and report any abnormalities. Use padding and positioning to relieve pressure. Treat any open areas according to facility guidelines and the surgeon's prescription. Ensure that information about the patient's skin condition in the PACU is communicated to the medical-surgical nurse.

Managing Pain

Planning: Expected Outcomes. The postoperative patient is expected to attain or maintain optimal comfort levels. Indicators include:

- Reporting that pain is controlled
- Absence of physiologic indicators of acute pain (increased heart rate and blood pressure)
- Absence of facial grimacing, teeth clenching
- Willingness to move and participate in self-care

Interventions. Pain management after surgery includes drug therapy and other methods of management, such as positioning, massage, relaxation techniques, and diversion. Often the patient has better pain relief from a combination of approaches. Assess the patient's comfort level and the effectiveness of the therapies. See [Chapter 5](#) for discussion of pain assessment and management. The patient who has optimal pain control is better able to cooperate with the therapies and exercises to prevent complications and promote rehabilitation.

Drug Therapy. *The use of opioids or other analgesics for pain management may mask or increase the severity of symptoms of an anesthesia reaction. Therefore give these drugs with caution, especially in the PACU when the patient's condition is not stable.* When pain drugs are used in the PACU, they are usually given IV in small doses. After receiving any drug for pain, the patient remains in the PACU for a defined period (often 45 to 60 minutes). Assess for hypotension, respiratory depression, and other side effects. Within 5 to 10 minutes after an IV injection, assess the effectiveness of the drug (i.e., on a rating scale) in relieving pain.

Opioid analgesics are given during the first 24 to 48 hours after surgery to control acute pain. Around-the-clock scheduling is more effective than “on demand” scheduling because more constant blood levels are achieved. Drugs commonly used include morphine (Statex ) , hydromorphone (Dilaudid), ketorolac (Toradol), codeine, butorphanol (Stadol), and oxycodone with aspirin (Percodan) or oxycodone with acetaminophen (Tylox, Percocet).

! NURSING SAFETY PRIORITY

Drug Alert

The usual dosage for hydromorphone is much smaller (about one-fifth to one-tenth) that of morphine.

Assess the type, location, and intensity of the pain before and after giving medication (see also [Discomfort/Pain Assessment](#), pp. 291-292). Monitor the patient's vital signs for hypotension and hypoventilation after giving opioid drugs. [Chart 18-6](#) lists information about analgesics used after surgery.

Patient-controlled analgesia (PCA) by IV infusion or internal pump (the catheter is sutured into or near the surgical area) and epidural analgesia are often used for better pain control. In PCA, the patient adjusts the dosage of the

analgesic based on the pain level and response to the drug. This method allows more consistent pain relief and more control by the patient. The maximum dose per hour is “locked in” to the pump so that the patient cannot accidentally overdose. The most common drugs given by the PCA method are morphine and hydromorphone.

Epidural analgesia can be given intermittently by the anesthesia provider or by continuous infusion through an epidural catheter left in place after epidural anesthesia. Drugs given by epidural catheter include the opioids fentanyl (Sublimaze), preservative-free morphine (Duramorph), and bupivacaine (Marcaine).

Take care not to overmedicate or undermedicate, especially with older patients. In assessing for overmedication, monitor vital signs, especially blood pressure and respiratory rate, and level of consciousness. Complications from the use of opioid analgesics include respiratory depression, hypotension, nausea, vomiting, and constipation. An opioid antagonist, such as naloxone (Narcan), may be needed to reverse the acute effects of opioid depression. Because of the short effect of the opioid antagonist, monitor the patient's blood pressure and respirations every 15 to 30 minutes until the full effect of the opioid analgesic has passed. You may need to give more doses of the antagonist during this time because it is eliminated from the body more quickly than is the opioid. (See [Chart 18-7](#) for more information on using opioid antagonists to reverse opioid overdose.) In addition, the patient has breakthrough pain after the opioid antagonist is given, so other interventions to promote comfort are needed.

Assess for undermedication by asking the patient about the effects of the drug and observing for nonverbal cues of pain or discomfort (e.g., restlessness, increased confusion, “picking” at bedcovers, aggressive behaviors). Offer prescribed pain drug(s) after checking for hypotension and respiratory depression.

As recovery progresses, reduce the doses and frequency of pain drugs. Drugs are changed from injectable or PCA to oral as soon as the patient can tolerate oral agents. Non-opioid analgesics, such as acetaminophen (Tylenol, Atasol ) , and NSAIDs, such as ibuprofen (Motrin, Novo-Profen ) , Amersol ) and ketorolac (Toradol), are used alone or with an opioid analgesic. Antianxiety drugs, such as hydroxyzine (Vistaril, Novo-Hydroxyzin ) , may be given with an opioid analgesic. This combination decreases pain-related anxiety, reduces muscle tension, and controls nausea.

! NURSING SAFETY PRIORITY

Drug Alert

Do not confuse Toradol with Tramadol (a drug used for central anesthesia).

Complementary and Alternative Therapies. Provide other comfort measures that may lower the amount of pain drugs needed. These measures, such as positioning, massage, relaxation, and diversion, reduce anxiety and allow the patient to relax and rest.

In positioning the patient, consider the position during surgery, the location of the surgical incision and drains, and problems such as arthritis and chronic lung disease. Assist the patient to a position of comfort. Support the extremities with pillows. Turn or help the patient turn at least every 2 hours

CHART 18-6 COMMON EXAMPLES OF DRUG THERAPY

Management of Postoperative Pain

DRUG	USUAL DOSAGE	NURSING INTERVENTIONS	RATIONALES
Morphine sulfate (Epimorph  , Stalex )	2-15 mg IM or IV incrementally 10-30 mg orally every 4 hr Maximum 6 doses	Monitor respiratory status. Monitor blood pressure. Assess for GI motility and urine output.	Respiratory depression can be severe and require medical intervention. Hypotension, constipation, and urinary retention can occur.
Hydromorphone hydrochloride (Dilaudid)	1-4 mg IV or IM every 3-4 hr 2-4 mg orally every 3-4 hr	Monitor respirations. Monitor blood pressure. Monitor for food intolerance. Monitor fluid and electrolyte balance. Assess GI motility.	Respiratory depression, hypotension, anorexia, nausea, vomiting, and constipation can occur.
Codeine sulfate, codeine phosphate (Paveral )	15-60 mg IM or orally every 4 hr Maximum 6 doses	Monitor respiratory status. Monitor for food intolerance. Monitor fluid and electrolyte balance. Assess GI motility.	Respiratory depression, nausea, and vomiting can occur. Constipation is common; prophylactic interventions may be indicated.
Butorphanol tartrate (Stadol)	1-4 mg IM every 3-4 hr 0.5-2 mg IV Maximum 6-8 doses	Monitor neurologic status and changes in level of consciousness. Monitor respiratory status.	Butorphanol can cause increased intracranial pressure and respiratory depression.
Oxycodone hydrochloride and aspirin (Percodan, Endodan  , Oxycodan )	1-2 tablets (5-10 mg) orally every 3-4 hr Maximum 80 mg	Assess GI tolerance of medication. Assess for GI bleeding. Monitor GI motility. Monitor coagulation studies (PT, aPTT). Monitor respiratory status.	The aspirin component can irritate the stomach and could cause GI bleeding. Bleeding times and other coagulation study results may be increased because of the aspirin component. Respiratory depression and constipation can be caused by the oxycodone component.
Oxycodone hydrochloride and acetaminophen (Tylox, Percocet, Endocet  , Oxycocet )	1-2 tablets (5-10 mg) orally every 3-4 hr Maximum 12 tablets	Monitor blood pressure and respiratory status. Assess for GI motility.	Respiratory depression, hypotension, and constipation can occur.
Ketorolac tromethamine (Toradol)	15-60 mg IM or IV every 6 hr Maximum 120 mg 5-day administration maximum	Monitor for GI bleeding. Monitor for renal effects, especially in older adults.	GI bleeding, ulceration, and perforation can occur. Decreased urine output, increased serum creatinine, hematuria, and proteinuria can occur. Ketorolac is cleared more slowly in older adults. Older persons are more sensitive to the renal effects of NSAIDs.
Ibuprofen (Motrin, Amersol  , Novoprofen )	300-800 mg orally every 4-6 hr Maximum 2400 mg daily	Monitor upper GI tolerance of medication. Give with food or milk. Monitor coagulation studies (PT, aPTT). Assess for signs of bleeding or delayed clotting.	Food or milk helps decrease irritation of the stomach. Bleeding times and other coagulation study results may be increased. Monitoring leads to early detection of complications.

aPTT, Activated partial thromboplastin time; GI, gastrointestinal; NSAID, nonsteroidal anti-inflammatory drug; PT, prothrombin time.

while he or she is bedridden to prevent complications caused by immobility.

! NURSING SAFETY PRIORITY**Action Alert**

Unless the surgeon prescribes pillow support, place no pillows under the knees, and do not raise the knee gatch, because this position could restrict circulation and increase the risk for venous thromboembolism.

Based on the surgeon's prescription and your assessment of the patient's tolerance, urge the patient to increase

activity progressively. Activity decreases stiffness, helps lung expansion, and promotes venous blood return. When he or she is first allowed out of bed, assist the patient to the side of the bed and into a chair. Teach him or her to splint the surgical wound for support and comfort during the transfer.

Use gentle massage on stiff joints or a sore back to decrease discomfort. Assist the patient to a side-lying position, and apply lotion with smooth, gentle strokes to increase blood flow to the area and promote relaxation. *Do not massage the calves because of the risk for loosening a clot and causing a life-threatening pulmonary embolus.*

CHART 18-7 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Emergency Care of the Patient Experiencing an Opioid Overdose

- Prepare to administer naloxone hydrochloride (Narcan)* in a dose of 1 to 2 mg IV.
- Repeat naloxone every 2 to 3 minutes up to 10 mg, as needed, depending on the patient's response.
- Maintain an open airway.
- Give oxygen if hypoxia is present or if respirations are below 10 breaths per minute.
- Have suction equipment available because naloxone can trigger vomiting and a drowsy patient is at risk for aspiration.
- Continuously monitor vital signs and level of consciousness for reversal of overdose.
- Do not leave the patient until he or she is fully responsive.
- Assess the patient for pain because reversal of the opioid overdose also reverses the analgesic effects.
- Continue to monitor the patient's vital signs and level of consciousness every 10 to 15 minutes for the first hour. Naloxone is eliminated from the body more quickly than is the opioid, and it may induce side effects, including blood pressure changes, tachycardia, and dysrhythmias.
- Determine the need for additional antagonist therapy 1 hour after the patient initially becomes fully responsive.

*There are other opioid antagonists; however, naloxone hydrochloride is used most often to manage adult opioid overdose in the postoperative period.

CHART 18-8 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Nonpharmacologic Interventions to Reduce Postoperative Pain and Promote Comfort

- Control or remove noxious stimuli.
- Cushion and elevate painful areas; avoid tension or pressure on those areas.
- Provide adequate rest to increase pain tolerance.
- Encourage the patient's participation in diversional activities.
- Instruct the patient in relaxation techniques; use audiotapes or CDs and breathing exercises.
- Provide opportunities for meditation.
- Help the patient stimulate sensory nerve endings near the painful areas to inhibit ascending pain impulses.
- Use ice to reduce and prevent swelling, as indicated.
- Find a general position of comfort for the patient.
- Help the patient stimulate the area contralateral (opposite) to the painful area.

Relaxation and diversion are also used to control acute episodes of pain that may occur during dressing changes and injections. [Chapters 2 and 5](#) discuss how to instruct and guide the patient through these pain control methods. Music and noise reduction have also been shown to decrease awareness of discomfort. [Chart 18-8](#) lists other interventions that may help reduce pain and promote comfort.

Community-Based Care

Many patients are discharged after a brief hospital stay or directly from the PACU to home. Because of the shortened length of hospital stays, discharge planning, teaching, and referral begin before surgery and continue after surgery.

Home Care Management

If the patient is discharged directly to home, assess information about the home environment for safety, cleanliness, and availability of caregivers. Use the database obtained on admission before surgery to determine the patient's needs. For example, if the patient is unable or not allowed to climb stairs and lives in a two-story house with only one bathroom, advise the patient to rent a bedside commode. Collaborate with the social worker or discharge planner to identify needs related to care after surgery, including meal preparation, dressing changes, drain management, drug administration, physical therapy, and personal hygiene. A referral to a home care nursing agency may be indicated.

The patient is usually concerned about complications, pain, changes in the usual activity level, or payment of the hospital bill. The more extensive the surgical procedure is, the more fearful the patient is of assuming self-care. Support the patient and family members as they make discharge plans. The patient with visible scars after surgery may need more emotional support from and acceptance by his or her family. The patient may be angry about the surgical outcome or about role changes. He or she may be concerned about financial matters and work. The surgical outcome may not have met the patient's expectations, and further interventions may be needed to assist in resolving his or her feelings. Ensure that referrals are made for additional counseling as indicated.

Teaching for Self-Management

The teaching plan for the patient and family after surgery includes:

- Prevention of infection
- Care and assessment of the surgical wound
- Management of drains or catheters
- Nutrition therapy
- Pain management
- Drug therapy
- Progressive increase in activity

If dressing changes and drain or catheter care are needed, instruct the patient and family members on the importance of proper handwashing to prevent infection. Explain and demonstrate wound care to the patient and family, who then perform a return demonstration. During teaching sessions, evaluate learning and promote adherence after discharge. At the same time, teach about the manifestations of complications such as wound infection. Also instruct the patient and family about what to do if complications occur.

A diet high in protein, calories, and vitamin C promotes wound healing. Supplemental vitamin C, iron, zinc, and other vitamins are often prescribed after surgery to aid in wound healing and red blood cell formation. Instruct the patient who needs dietary restrictions about the importance of following the prescribed diet while recovering from surgery. Encourage the older adult or debilitated patient to continue using dietary supplements, if prescribed, between meals until the wound is completely healed and the energy levels are restored.

Teach the patient about drugs for pain, especially about the proper dosage and frequency. Instruct the patient to notify the surgeon if pain is not controlled or if the pain suddenly increases. If antibiotics or other drugs are prescribed, stress the importance of completing the entire prescription.

Surgery stresses the body, and time and rest are needed for healing. Teach the patient to increase activity level slowly, rest often, and avoid straining the wound or the surrounding area. The surgeon decides when the patient may climb stairs, return to work, drive, and resume other usual activities, such as sexual intercourse. The amount of weight that the patient can lift safely after surgery is specifically defined by the surgeon (i.e., in pounds or kilograms). Remind patients of the weights of grocery bags, women's handbags, laundry baskets, children, and books.

Instruct the patient in the use of proper body mechanics. A patient whose work involves a moderate amount of physical labor may return to work about 6 weeks after abdominal surgery. However, he or she may be eager to return to normal activities and may not follow restrictions. Stress the importance of adherence to prevent complications or disability. A referral for a home care nurse may be needed for follow-up.

NURSING SAFETY PRIORITY

Action Alert

Always ensure that the patient and family receive written discharge instructions to follow at home.

Health Care Resources

After returning home, the patient may need supplies or equipment and assistance with dressing changes, ADLs, and meal preparation. Referral to a home care agency is made if needed. Home care may be paid for by third-party insurance payers, including Medicare, if the patient is homebound and requires skilled care such as dressing changes or physical therapy. The home care nurse provides skilled nursing assessments, dressing supplies, education in self-care, and referrals for services as needed. Such referrals include Meals on Wheels, support groups, and homemaker services (e.g., for housekeeping, food shopping).

EVALUATION: OUTCOMES

Evaluate the care of the patient after surgery based on the identified priority patient problems. The expected outcomes include that the patient:

- Attains and maintains adequate lung expansion and respiratory function
- Has complete wound healing without complications
- Has acceptable comfort levels after surgery

Specific indicators for these outcomes are listed for each priority patient problem in the Planning and Implementation section (see earlier).

GET READY FOR THE NCLEX® EXAMINATION!

KEY POINTS

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Use aseptic technique during all dressing changes.
- Use established criteria to determine when a patient is ready to leave the postanesthesia care unit (PACU) for discharge to home or a medical-surgical nursing unit.
- Keep suction equipment, oxygen, and artificial breathing equipment near the patient in the PACU.

Health Promotion and Maintenance

- Reinforce to the patient after surgery the specific interventions to use to prevent complications (incision splinting, deep-breathing exercises, range-of-motion exercises—as described in [Charts 16-5](#) and [16-6](#) in [Chapter 16](#)).
- Encourage early ambulation.
- Stress the need for following the activity restrictions prescribed by the surgeon.

Psychosocial Integrity

- Explain all procedures, restrictions, drugs, and follow-up care to the patient and family.
- Allow the patient to express feelings about any change in physical appearance or lifestyle as a result of surgery.

- Reassure patients that taking pain medication when needed, even opioids, does not make them drug abusers.
- Remain with the patient if wound dehiscence or evisceration occurs.
- Offer alternative therapies for relaxation, pain reduction, and distraction, such as massage, music therapy, and guided imagery.

Physiological Integrity

- Begin every assessment of the patient after surgery by checking the airway and breathing effectiveness.
- Assess the incision site each shift (on the medical-surgical nursing unit).
- In the event of wound dehiscence or evisceration, have the patient lie flat (supine) with knees bent to reduce intra-abdominal pressure; apply sterile, nonadherent dressing materials to the wound; and follow the steps outlined in [Chart 18-5](#).
- Teach the patient about any drugs to be continued after discharge from the facility.
- Instruct the patient and family about the clinical manifestations of complications and when to seek assistance.

CONCEPT OVERVIEW

Protection

The human body works best when the internal environment is kept separate from the external environment. This is especially important for substances and organisms that could harm body cells, tissues, and organs. Normal protection is provided by three types of defenses—similar to how people living in a castle are protected against invaders (Fig. 1).

FIG. 1 Three levels of protection (moat, castle wall, knights and soldiers) for people.

The first defense is the moat surrounding the castle walls. Although the moat seldom kills invaders directly, it at least slows them down and sometimes repels them. The human “moat” is the normal flora on the surface of the skin and mucous membranes. This normal flora is made up of bacteria and other organisms that belong on the skin, live peacefully with the human host, and help repel more harmful microorganisms. When the normal flora is changed as a result of some types of drug therapy, procedures, diseases, excessive dryness, and normal aging, this small protection is damaged or lost.

The second defense is the castle wall and the “watchers” and alarm systems embedded within it. When it is tall, thick, and intact and when the watchers and alarms are working, penetration of the castle by invaders is greatly reduced. In humans, this type of protection is provided by intact skin and mucous membranes. These structures are a formidable barrier to invaders and help prevent dangerous changes in the internal environment. However, the castle walls do suffer some damage over time and must be repaired and maintained to provide continuing protection.

The last and strongest defense consists of the knights and soldiers within the castle. These individuals have the skills to capture or kill invaders. Some of these skills are common to all the knights and soldiers, and others are unique to different groups. In humans, the white blood cells (leukocytes) and the substances they produce serve as knights and soldiers. In addition to the work related directly to the invaders, this defense helps repair and maintain the castle walls. It is important to remember that this level of protection relies on the alarms of the castle wall and its physical barrier to recognize invaders and trigger the protective responses of the knights and soldiers.

Protection occurs best when all three defenses are intact and are working at their highest functional levels. These defenses begin at birth and are at the maximum function in early to middle adulthood. The defenses decline slowly over time, making an older adult at greater risk for illnesses related to invasion and a decreased ability to repair damage. External factors and health status can reduce the ability of these defenses to provide complete protection. Specific nursing strategies can help reduce risk and protect the person whose defenses are less than perfect.

Key Points

Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

Physiological Integrity

1. Describe the concept of self-tolerance.
2. Explain the differences between inflammation and immunity in terms of cells, functions, and features.
3. Use knowledge of physiology to describe the basis for the five cardinal manifestations of inflammation.
4. Discuss the influences of the aging process on inflammation and immunity and how these changes increase health risks for older adults.
5. Interpret a white blood cell count with differential to indicate no immune problems, immune suppression, infection, or an allergic reaction.
6. Differentiate the protection provided by active immunity, passive immunity, and cell-mediated immunity.
7. Describe the expected immune system responses to the presence of transplanted organs and the need for drug therapy to prevent transplant rejection.

Inflammatory responses and the immune system work with other defenses to provide *protection* from harmful microorganisms and cells. As indicated in the section opener defining the *concept of protection*, the cells and cell products of inflammation and immunity are represented mostly by the knights and soldiers behind the castle walls. The products made by cells, such as cytokines, growth factors, and antibodies, are the weapons of the knights and soldiers. In addition, some of

these cells serve as watchers and alarm systems actually within the castle walls (skin and mucous membranes). They also help maintain and repair these walls when damage occurs.

Infectious diseases are common. Most people, however, are healthy more often than they are ill. Inflammation and immunity are the major defenses that protect against disease when the body is invaded by organisms. These same defenses also help the body recover after tissue damage. For these

reasons, inflammation and immunity are critical to maintaining health and preventing disease. When all the different parts and functions of inflammation and immunity are working well, the person is **immunocompetent** and has maximum protection against infection.

Immune function is reduced by many diseases, injuries, and medical therapies. *Reduction of immune function may be temporary or permanent, but it always endangers the patient's health.* Chapter 21 discusses issues related to reduced protection from inadequate immunity or inflammatory responses. Other problems occur when immunity overfunctions or functions at inappropriate times, at which time this normally protective response becomes an enemy (Braun, 2010; Stevens, 2009). Chapters 20 and 22 discuss issues related to damage from excess or inappropriate inflammatory or immune responses.

OVERVIEW

Immunity is composed of many cell functions that protect people against the effects of injury or invasion. People interact with many other living organisms in the environment. The size of these organisms varies from large (other humans and animals) to microscopic (bacteria, viruses, molds, spores, pollens, protozoa, and cells from other people or animals). As long as organisms do not enter the body, they pose no health threat. The body has some defenses to prevent organisms from entering, such as intact skin and mucous membranes, skin surface normal flora, and natural chemicals that inhibit bacterial growth. These defenses are not perfect, and invasion of the body by organisms occurs often. Invasion occurs much more often than does an actual disease or illness because of proper immune functioning.

The purpose of inflammation and immunity is to provide *protection* by neutralizing, eliminating, or destroying organisms that invade the internal environment. To protect without

harming the body, immune system cells use protective actions only against non-self proteins and cells. Immune system cells can distinguish between the body's own healthy self cells and other, non-self proteins and cells.

Self Versus Non-Self

Non-self proteins and cells include infected body cells, cancer cells, cells from other people, and invading organisms. Recognizing self versus non-self, which is necessary to prevent healthy body cells from being destroyed along with the invaders, is called **self-tolerance**. The immune system cells are the only cells capable of determining self from non-self. Self-tolerance is possible because of the different proteins present on cell membranes.

Each cell is surrounded by a plasma membrane with different proteins protruding through the surface (Fig. 19-1). For example, in liver cells, many different protein types are present on the cell membrane surface. The amino acid sequence of each protein type differs from that of all other protein types. Some of these proteins are found on the liver cells of all animals (including humans) that have livers, because these protein types are specific to the liver and serve as a *marker* for liver tissues. Other protein types are found only on the liver cells of humans, because these protein types are specific markers for human tissues. In addition, each person's liver cells have surface proteins that are specific to that person. These unique proteins would be identical only to the proteins of an identical sibling. These unique proteins, known as **human leukocyte antigens (HLAs)**, are found on the surface of all body cells of that person and serve as a “universal product code” or a “cellular fingerprint” for that person. One person's HLAs are recognized as “foreign,” or non-self, by the immune system of another person. Because the cell-surface proteins are non-self to another person's immune system, they are **antigens**, which are proteins capable of stimulating an immune response.

FIG. 19-1 Proteins on human cell plasma membranes.

Human leukocyte antigens are on the surfaces of most body cells—not just on leukocytes. They are a normal part of the person and act as antigens only if they enter another person's body. These antigens determine the *tissue type* of a person. Other names for these cellular fingerprints are *human transplantation antigens*, *human histocompatibility antigens*, and *class I antigens*.

Humans have about 40 major HLAs that are determined by a set of genes called the *major histocompatibility complex (MHC)*. The specific antigens that any person has (of a large number of possible antigens) are determined by which MHC gene alleles were inherited from his or her parents (Nussbaum et al., 2007).

The HLAs are key for recognition and self-tolerance. The immune system cells constantly come into contact with other body cells and with any invader that enters the body. At each encounter, the immune system cells compare the surface protein HLAs to determine whether the encountered cell belongs in the body (Fig. 19-2). If the encountered cell's HLAs perfectly match the HLAs of the immune system cell,

FIG. 19-2 Determination by immune system cell of self versus non-self cells.

the encountered cell is “self” and is not attacked by the immune system cell. If the encountered cell's HLAs do not perfectly match the HLAs of the immune system cell, the encountered cell is non-self, or foreign. The immune system cell then takes action to neutralize, destroy, or eliminate this foreign invader.

Immune function changes during a person's life, according to nutritional status, environmental conditions, drugs, disease, and age. Immune function is most efficient when people are in their 20s and 30s and slowly declines with increasing age (Graham et al., 2006; Touhy & Jett, 2010). Older adults have decreased immune function, increasing their risk for many health problems (Chart 19-1).

Organization of the Immune System

The immune system is not located in any one body area but, rather, is influenced by many systems, especially the nervous system, the endocrine system, and the GI system. Most immune system cells come from the bone marrow. Some cells mature in the bone marrow; others leave the bone marrow and mature in different body sites. When mature, many immune system cells are released into the blood, where they circulate to most body areas and have specific effects.

The bone marrow is the source of all blood cells, including immune system cells. The bone marrow produces immature, undifferentiated cells called **stem cells** (Abbas et al., 2010; Kaufman, 2011). Stem cells are **pluripotent**, meaning that each cell has more than one potential outcome. When the stem cell is first created in the bone marrow, it is undifferentiated. The cell is not yet committed to maturing into a specific blood cell type. At this stage, the stem cell is flexible (pluripotent) and could become any one of many mature blood cells. Fig. 19-3 shows the possible outcomes for maturation of stem cells. The type of mature cell that the stem cell becomes depends on which pathway it follows.

The maturational pathway of any stem cell depends on body needs and on the presence of specific growth factors

CHART 19-1 NURSING FOCUS ON THE OLDER ADULT

Changes in Immune Function Related to Aging

IMMUNE COMPONENT	FUNCTIONAL CHANGE	NURSING IMPLICATIONS
Inflammation	There is a probable defect in neutrophil function. Leukocytosis does not occur during episodes of acute infection. Older adults may not have a fever during inflammatory or infectious episodes.	Neutrophil counts may be normal, but activity is reduced or impaired, increasing the risk for infection. Patients may have an infection but not show expected changes in white blood cell counts. Not only is there potential loss of protection through inflammation, but also minor infections may be overlooked until the patient becomes severely infected or septic.
Antibody-mediated immunity	The total number of colony-forming B-lymphocytes and the ability of these cells to mature into antibody-secreting cells are diminished. There is a decline in natural antibodies, decreased response to antigens, and reduction in the amount of time the antibody response is maintained.	Older adults are less able to make new antibodies in response to the presence of new antigens. Thus they should receive immunizations, such as “flu shots,” the pneumococcal vaccination, and the shingles vaccination. Older adults may not have sufficient antibodies present to provide protection when they are re-exposed to microorganisms against which they have already generated antibodies. Thus older patients need to avoid people with viral infections and need to receive “booster” shots for old vaccinations and immunizations, especially tetanus and pertussis (whooping cough).
Cell-mediated immunity	Thymic activity decreases with aging, and the number of circulating T-lymphocytes decreases.	Skin tests for tuberculosis may be falsely negative. Older patients are more at risk for bacterial and fungal infections, especially on the skin and mucous membranes, in the respiratory tract, and in the genitourinary tract.

that direct the cell to a pathway. For example, erythropoietin is a growth factor for red blood cells (RBCs). When immature stem cells are exposed to erythropoietin, they commit to the erythrocyte pathway and eventually become mature RBCs.

White blood cells (**leukocytes or WBCs**) protect the body from the effects of invasion by organisms. These cells are the immune system cells—the knight and soldiers protecting the castle inhabitants after invaders get through the castle wall. Table 19-1 lists the functions of different immune system cells. The leukocytes provide protection through many defensive actions (Abbas et al., 2010; Stevens, 2009). These actions include:

- Recognition of self versus non-self
- Destruction of foreign invaders, cellular debris, and unhealthy or abnormal self cells
- Production of antibodies directed against invaders
- Complement activation
- Production of cytokines that stimulate increased formation of leukocytes in bone marrow and increase specific leukocyte activity

The three processes needed for human protection through immunity are (1) inflammation, (2) antibody-mediated immunity (AMI), and (3) cell-mediated immunity (CMI). Each process uses different defensive actions, and each influences or requires assistance from the other two processes (Fig. 19-4). Therefore full immunity (*immunocompetence*) requires the function and interaction of all three processes.

INFLAMMATION

Inflammation, also called *innate-native immunity* or *natural immunity*, provides immediate protection against the effects of tissue injury and invading foreign proteins. Innate-native immunity is any natural protective feature of a person. It can be a barrier to prevent organisms from entering the body or can be an attacking force that eliminates organisms that have already entered the body. This type of immunity cannot be developed or transferred from one person to another and is not an adaptive response to exposure or invasion by foreign proteins.

The inflammatory responses are part of innate immunity. Other parts of innate immunity include skin, mucosa, antimicrobial chemicals on the skin, complement, and natural killer cells (Abbas et al., 2010; Stevens, 2009).

The ability to produce an inflammatory response is critical to health and well-being. Inflammation differs from AMI and CMI in two important ways:

- Inflammatory protection is immediate but short-term against injury or invading organisms. It does not

TABLE 19-1 IMMUNE FUNCTIONS OF SPECIFIC LEUKOCYTES

VARIABLE	LEUKOCYTE	FUNCTION
Inflammation	Neutrophil	Nonspecific ingestion and phagocytosis of microorganisms and foreign protein
	Macrophage	Nonspecific recognition of foreign proteins and microorganisms; ingestion and phagocytosis
	Monocyte	Destruction of bacteria and cellular debris; matures into macrophage
	Eosinophil	Weak phagocytic action; releases vasoactive amines during allergic reactions
	Basophil	Releases histamine and heparin in areas of tissue damage
Antibody-mediated immunity	B-lymphocyte	Becomes sensitized to foreign cells and proteins
	Plasma cell	Secretes immunoglobulins in response to the presence of a specific antigen
	Memory cell	Remains sensitized to a specific antigen and can secrete increased amounts of immunoglobulins specific to the antigen on re-exposure
Cell-mediated immunity	Helper/inducer T-cell	Enhances immune activity through secretion of various factors, cytokines, and lymphokines
	Cytotoxic/cytolytic T-cell	Selectively attacks and destroys non-self cells, including virally infected cells, grafts, and transplanted organs
	Natural killer cell	Nonselectively attacks non-self cells, especially body cells that have undergone mutation and become malignant; also attacks grafts and transplanted organs

FIG. 19-3 Stem cell differentiation and maturation.

provide true immunity on repeated exposure to the same organisms.

- Inflammation is a *nonspecific* body defense to invasion or injury and can be started quickly by almost any event, regardless of where it occurs or what causes it.

So, inflammation triggered by a scald burn to the hand is the same as inflammation triggered by bacteria in the middle ear. How widespread the symptoms of inflammation are depends on the intensity, severity, and duration of exposure to the initiating event. For example, a splinter in the finger triggers inflammation only at the splinter site, whereas a burn injuring 50% of the skin leads to an inflammatory response involving the entire body.

Inflammatory responses start tissue actions that cause visible and uncomfortable symptoms. Despite the discomfort, these actions are important in ridding the body of harmful organisms. However, if the inflammatory response is excessive, tissue damage may result (Landis, 2009). Inflammatory responses also help start both antibody-mediated and cell-mediated actions to activate a full immune response.

FIG. 19-4 The three divisions of immunity: inflammation, antibody-mediated immunity, and cell-mediated immunity. Optimal function of all three divisions is necessary for complete immunity.

Infection

A confusing issue about inflammation is that this process occurs in response to tissue injury, as well as to invasion by organisms. *Infection is usually accompanied by inflammation; however, inflammation can occur without infection.* Examples of inflammation without infection include joint sprain injuries, myocardial infarction, and blister formation. Examples of inflammation caused by noninfectious invasion include allergic rhinitis, contact dermatitis, and other allergic reactions. Inflammations from infection include otitis media, appendicitis, and viral hepatitis, among many others. *Inflammation does not always mean that an infection is present.*

Cell Types Involved in Inflammation

The leukocytes involved in inflammation are neutrophils, macrophages, eosinophils, and basophils. Neutrophils and macrophages use phagocytosis to destroy and eliminate foreign invaders. Basophils and eosinophils release chemicals that act on blood vessels to cause tissue-level responses that help neutrophil and macrophage actions.

Neutrophils

Mature neutrophils make up between 55% and 70% of the normal total white blood cell (WBC) count. Neutrophils come from the stem cells and complete the maturation process in the bone marrow (Fig. 19-5). They are also called *granulocytes* because of the large number of granules present inside each cell. Other names for neutrophils are based on their appearance and maturity. Mature neutrophils are also called *segmented neutrophils* (“segs”) or *polymorphonuclear cells* (“polys,” PMNs) because of their segmented nucleus. Less mature neutrophils are called *band neutrophils* (“bands” or “stabs”) because of their nuclear shape.

Usually, growth of a stem cell into a mature neutrophil requires 12 to 14 days. This time is shortened by the presence of specific growth factors (cytokines), such as granulocyte-macrophage colony-stimulating factor (GM-CSF) and granulocyte colony-stimulating factor (G-CSF). The purpose and action of cytokines are described on p. 314 in the Cytokines section.

In the immunocompetent healthy person, more than 100 billion fresh, mature neutrophils are released from the bone marrow into the circulation daily (Abbas et al., 2010; Stevens, 2009). This huge production is needed because the life span of each neutrophil is short—about 12 to 18 hours.

FIG. 19-5 Stem cell maturation into fully functional segmented neutrophils.

Neutrophil function provides protection after invaders, especially bacteria, enter the body. Although the neutrophils are the largest group of circulating leukocytes, each cell is small. This powerful army destroys invaders by phagocytosis and enzymatic digestion, although each cell is small and can take part in only one episode of phagocytosis.

Mature neutrophils are the only stage of this cell capable of phagocytosis. Because this cell type is responsible for continuous, instant, nonspecific protection against organisms, the percentage and actual number of mature circulating neutrophils are used to measure a patient's risk for infection: the higher the numbers, the greater the resistance to infection. This measurement is the **absolute neutrophil count (ANC)**, also called the *absolute granulocyte count* or *total granulocyte count*.

The differential of a normal white blood cell count shows the number and percent of the different types of circulating leukocytes (Table 19-2). Usually, most neutrophils released into the blood from the bone marrow are segmented neutrophils; only a small percentage are band neutrophils. Less mature neutrophil forms should not be in the blood. Some problems, such as sepsis, cause the neutrophils in the blood to change from being mostly segmented neutrophils to being less mature forms. This situation is termed a **left shift** or *bandemia* because the segmented neutrophil, which is seen at the far right of the neutrophil pathway (see Fig. 19-5), is no longer the most numerous type of circulating neutrophils. Instead, more of the circulating cells are bands—the less mature cell type found farther left on the neutrophil pathway.

A left shift indicates that the patient's bone marrow cannot produce enough mature neutrophils to keep pace with the continuing infection and is releasing immature neutrophils into the blood. Unfortunately, most of these immature cells are of no benefit because they are not capable of phagocytosis.

Macrophages

Macrophages come from the committed myeloid stem cells in the bone marrow and form the mononuclear-phagocyte system. The stem cells first form monocytes, which are released into the blood at this stage. Until they mature, monocytes have limited activity. Most monocytes move from the blood into body tissues, where they mature into macrophages. Some macrophages become “fixed” in position within the tissues, whereas others can move within and between tissues. Macrophages in various tissues have slightly different appearances and names (Table 19-3). The liver, spleen, and intestinal tract contain large numbers of these cells.

TABLE 19-2 VALUES OF A WHITE BLOOD CELL DIFFERENTIAL FOR PERIPHERAL BLOOD REPRESENTING A NORMAL COUNT

WBC TYPE	%	/MM ³
TOTAL WBC	100	10,000
Segs	62	6200
Bands	5	500
Monos	3	300
Lymphs	28	2800
Eosins	1.5	150
Basos	0.5	50

Macrophage function provides protection in several ways. These cells are important in immediate inflammatory responses and also stimulate the longer-lasting immune responses of antibody-mediated immunity (AMI) and cell-mediated immunity (CMI). Specific macrophage functions include phagocytosis, repair, antigen presenting/processing, and secretion of cytokines that help control the immune system.

The inflammatory function of macrophages is phagocytosis. Macrophages can easily distinguish between self and non-self, and their large size makes them very effective at trapping invading cells. Unlike neutrophils, macrophages have long life spans and can take part in many phagocytic events.

Basophils

Basophils come from myeloid stem cells and make up only about 1% of the total circulating WBC count. These cells cause the manifestations of inflammation.

Basophil function results in actions on blood vessels through the activity of basophil chemicals (vasoactive amines). These chemicals include heparin, histamine, serotonin, kinins, and leukotrienes. When released into the blood, most of these chemicals act on smooth muscle and blood vessel walls. Heparin inhibits blood and protein clotting. Histamine constricts small veins, inhibiting blood flow and decreasing venous return. This effect causes blood to collect in capillaries and arterioles. Kinins dilate arterioles and increase capillary permeability. These actions cause blood plasma to leak into the interstitial space (*vascular leak syndrome*).

Eosinophils

Eosinophils come from the myeloid line and contain many vasoactive chemicals. Usually, only 1% to 2% of the total white blood cell (WBC) count is composed of eosinophils.

Eosinophil function is very active against infestations of parasitic larvae and also limits inflammatory reactions. The eosinophil granules contain many different substances. Some are enzymes that degrade the vasoactive chemicals released by other leukocytes. This is why the number of circulating eosinophils increases during an allergic response.

Phagocytosis

A key process of inflammation is **phagocytosis**, the engulfing and destruction of invaders. This action also rids the body of debris after tissue injury. Neutrophils and macrophages are most efficient at phagocytosis. Phagocytosis involves the seven steps shown in Fig. 19-6.

TABLE 19-3 TISSUE MACROPHAGES

TISSUE	MACROPHAGE
Lung	Alveolar macrophage
Connective tissue	Histiocyte
Brain	Microglial cell
Liver	Kupffer cell
Peritoneum	Peritoneal macrophage
Bone	Osteoclast
Joint	Synovial type A cell
Kidney	Mesangial cell

FIG. 19-6 Steps of phagocytosis.

Exposure and invasion occur as the first step. Leukocytes that engage in phagocytosis and stimulate inflammation are present in the blood and other extracellular fluids. For phagocytosis to start, the body must first be invaded by organisms, foreign proteins, or debris from damaged tissues. The process is triggered by injury or invasion.

Attraction is needed as the second step because phagocytosis can occur only when the WBC comes into direct contact with the target (antigen, invader, or foreign protein). Some substances (**chemotaxins**) attract neutrophils and macrophages. Damaged tissues secrete chemotaxins and release debris that can combine with the surface of invading foreign proteins.

Adherence is important because phagocytosis requires that the phagocytic cell first bind to the surface of the target. *Opsonins* are substances that increase contact of the cell with its target by coating the target cell (antigen or organism). During inflammation, coating the target makes it easier for phagocytic cells to stick to it. Many substances can act as opsonins. Some are particles from dead neutrophils, antibodies, and activated (fixated) complement components.

Complement activation and fixation are part of opsonization and help with adherence. Twenty different types of inactive complement proteins are present in the blood. When stimulated, each complement protein is activated, joins other activated complement proteins, surrounds an antigen, and “fixes” or sticks to the antigen. Complement fixation occurs quickly as a cascade or chain reaction.

Recognition occurs when the phagocytic cell sticks to the surface of the target cell and “recognizes” it as non-self. The phagocytic cells examine the universal product codes (human leukocyte antigens [HLAs]) of whatever they encounter. Recognition of non-self is made easier by opsonins on the target cell surface. Phagocytic cells start phagocytosis only when the target cell is recognized either as non-self or as debris from damaged self cells.

Cellular ingestion is needed because phagocytic destruction occurs inside the cell. The target cell is brought inside the phagocytic cell by phagocytosis (engulfment). The phagocytic cell bends its membrane around to enclose (engulf) the target cell and form a vacuole.

Phagosome formation occurs when the phagocyte’s granules are inside the vacuole. These granules break and release enzymes that attack the ingested target.

Degradation is the final step. The enzymes in the phagosome digest the engulfed target. The target is broken into smaller pieces until only small particles of debris remain.

Sequence of Inflammatory Responses

Inflammatory responses occur in a predictable sequence of three stages. The sequence is the same regardless of the triggering event. Responses at the tissue level cause the **five cardinal manifestations of inflammation**: warmth, redness, swelling, pain, and decreased function. The timing of the stages may overlap.

Stage I is the vascular part of the inflammatory response. In this stage, the early effects involve changes in blood vessels. Injured tissues and the leukocytes in this area secrete histamine, serotonin, and kinins that constrict the small veins and dilate the arterioles in the area of injury. These blood vessel changes cause redness and warmth of the tissues. This increased blood flow increases delivery of nutrients to injured tissues.

Blood flow to the area increases (**hyperemia**) and **edema** (swelling) forms at the site of injury or invasion. Capillary leak also occurs, allowing blood plasma to leak into the tissues. This response causes swelling and pain. Edema at the site of injury or invasion protects the area from further injury by creating a cushion of fluid. The extra fluid also can dilute any toxins or organisms that have entered the area. The duration of these responses depends on the severity of the initiating event, but usually they subside within 24 to 72 hours.

The macrophage is the major cell involved in stage I of inflammation. The action is rapid because macrophages are already in place at the site of injury or invasion. This action is limited because the number of macrophages is so small. To enhance the inflammatory response, the tissue macrophages secrete several cytokines. One cytokine is colony-stimulating factor (CSF), which triggers the bone marrow to shorten the length of time needed to produce white blood cells (WBCs) from 14 days to a matter of hours. Some of the cytokines also increase the release of neutrophils from the bone marrow and attract them to the site of injury or invasion, which leads to the next stage of inflammation.

Stage II is the cellular exudate part of the response. In this stage, **neutrophilia** (an increased number of circulating neutrophils) occurs. Exudate in the form of pus occurs, containing dead WBCs, necrotic tissue, and fluids that escape from damaged cells.

The most active cell in this stage is the neutrophil. Under the influence of cytokines, the neutrophil count can increase up to five times within 12 hours after the onset of inflammation. At the site of inflammation, neutrophils attack and destroy organisms and remove dead tissue through phagocytosis.

In acute inflammation, the healthy person produces enough mature neutrophils to keep pace with invasion and prevent the organisms from growing. At the same time, the WBCs and inflamed tissues secrete cytokines, which allow tissue macrophages to increase and trigger bone marrow production of monocytes. This reaction begins slowly, but its effects are long lasting.

During this phase, the arachidonic acid cascade starts to increase the inflammatory response. This action begins by the conversion of fatty acids in plasma membranes into

arachidonic acid (AA). The enzyme *cyclooxygenase* (COX) converts AA into many chemicals that are further processed into the substances that continue the inflammatory response in the tissues. Some of these substances (known as “mediators” because they promote continued inflammatory responses) include histamine, leukotrienes, prostaglandins, serotonin, and kinins. Many anti-inflammatory drugs, including NSAIDs, stop this cascade by preventing cyclooxygenase from converting AA into inflammatory mediators.

When an infection stimulating inflammation lasts longer than just a few days, the bone marrow cannot produce and release enough mature neutrophils to keep pace with the growth of organisms. In this situation, the bone marrow begins to release immature neutrophils, reducing the number of circulating mature neutrophils. This reduction of mature neutrophils limits the helpful effects of inflammation and increases the risk for sepsis.

Stage III features tissue repair and replacement. Although this stage is completed last, it begins at the time of injury and is critical to the final function of the inflamed area.

Some of the WBCs involved in inflammation start the replacement of lost tissues or repair of damaged tissues by inducing the remaining healthy cells to divide. In tissues that cannot divide, WBCs trigger new blood vessel growth (*angiogenesis*) and scar tissue formation. Because scar tissue does not behave like the tissue it replaces, function is lost wherever scar tissue forms. The degree of function lost depends on how much normal tissue is replaced by scar tissue. For example, when heart muscles are destroyed because of a myocardial infarction (heart attack), scar tissue forms in the area to prevent a hole from forming in the muscle wall as the ischemic cells die. (Remember that heart muscle is non-dividing tissue and the heart cannot replace these muscle cells.) The scar tissue serves only as a patch; it does not contract or act in any way like heart muscle. So, if 20% of the left ventricle is replaced with scar tissue, the effectiveness of left ventricular contraction is reduced by at least 20%.

Inflammation alone cannot provide immunity. Inflammatory cells must interact with lymphocytes to provide long-lasting immunity. Long-lasting immune actions develop through antibody-mediated immunity (AMI) and cell-mediated immunity (CMI).

IMMUNITY

Immunity is an *adaptive* internal protection that results in long-term resistance to the effects of invading microorganisms. This means that the responses are not automatic. The body has to learn to generate specific immune responses when it is infected by or exposed to specific organisms. Lymphocytes develop actions and products that provide the protection of true immunity. These cells develop specific actions in response to specific invasion (Fig. 19-7).

Antibody-Mediated Immunity

Antibody-mediated immunity (AMI), also known as *humoral immunity*, involves antigen-antibody interactions to neutralize, eliminate, or destroy foreign proteins. Antibodies are produced by sensitized B-lymphocytes (B-cells).

B-cells become sensitized to a specific foreign protein (antigen) and produce antibodies directed specifically against that protein. The antibody, rather than the actual B-cell, then

FIG. 19-7 B-lymphocyte and T-lymphocyte differentiation, maturation, and function.

causes one of several actions to neutralize, eliminate, or destroy that antigen.

B-cells have the most direct role in AMI. Macrophages and T-lymphocytes (discussed on p. 313 in the Cell-Mediated Immunity section) work with B-cells to start and complete antigen-antibody interactions. *For optimal AMI, the entire immune system must function adequately.*

B-cells start as stem cells in the bone marrow, the primary lymphoid tissue. Those stem cells that become B-cells commit early to the lymphocyte pathway (see Fig. 19-3) and are then restricted in development. The lymphocyte stem cells are released from the bone marrow into the blood. They then migrate into many secondary lymphoid tissues, where maturation is completed. The secondary lymphoid tissues for B-cell maturation are the spleen, parts of lymph nodes, tonsils, and the mucosa of the intestinal tract.

Antigen-Antibody Interactions

The body learns to make enough of any specific antibody to provide long-lasting immunity and protection against specific organisms or toxins. Seven steps are needed to produce a specific antibody directed against a specific antigen

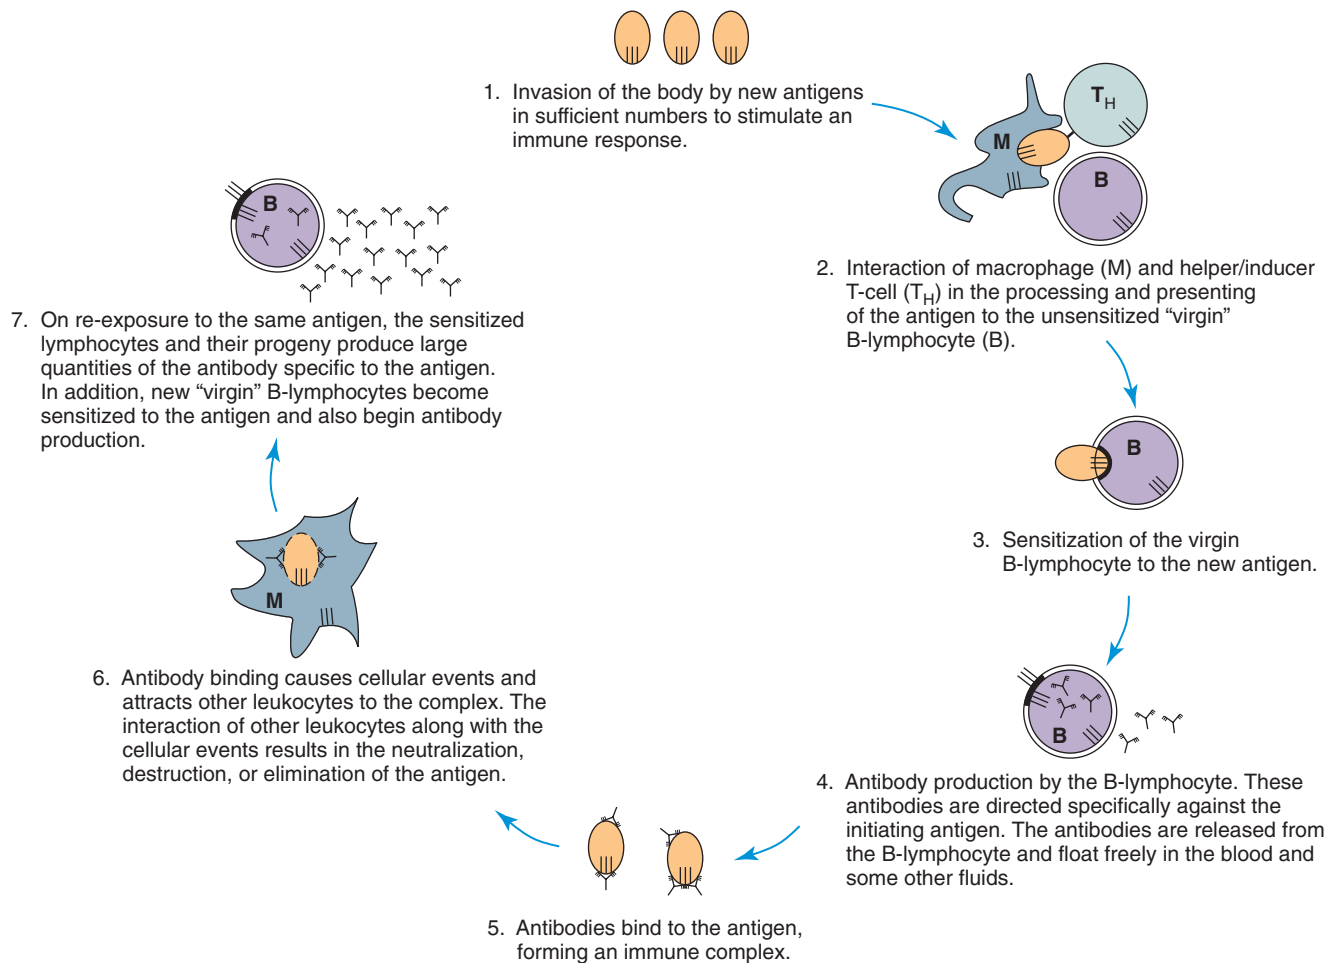

FIG. 19-8 Sequence of the seven steps required to stimulate antibody-mediated immunity.

whenever the person is exposed to that antigen. These steps are exposure (invasion), antigen recognition, lymphocyte sensitization, antibody production and release, antigen-antibody binding, antibody-binding reactions, and sustained immunity, or memory (Fig. 19-8).

Exposure or invasion is needed because antibody actions occur inside the body or on a few body surfaces. For a person to make an antibody that can exert its effects on a specific antigen, the antigen must first enter the person. Not all exposures or invasions result in antibody production. Invasion by the antigen must occur in such large numbers that some of the antigen evades detection by the body's natural nonspecific defenses or overwhelms the ability of the inflammatory response to get rid of the invader.

Take, for example, a person who has never been exposed to the childhood viral disease *chickenpox*. This person babysits for three children who develop chickenpox lesions within the next 10 hours. These children, in the pre-eruption stage, shed many millions of live chickenpox virus particles by droplets from the upper respiratory tract. Because small children are often unconcerned about the finer points of infection control, they drink out of the baby-sitter's cup, kiss him or her directly on the lips, and sneeze and cough directly into his or her face. During the 5 hours spent with the children, the baby-sitter is heavily invaded by the chickenpox virus (varicella-zoster) and will become sick with this disease

within 14 to 21 days. While the virus is growing and the disease is developing, the baby-sitter's white blood cells are taking part in antibody-antigen actions to prevent him or her from having chickenpox more than once.

Antigen recognition is the next step to begin making antibodies against an antigen. The unsensitized B-cell must first recognize the antigen as non-self. B-cells need the help of macrophages and helper/inducer T-cells to recognize an antigen.

Recognition is started by the macrophages. After the antigen surface has been altered by opsonization (see discussion of *adherence* on p. 308), the macrophage recognizes the invading antigen as non-self and physically attaches itself to the antigen. This attachment does not result in phagocytosis or in antigen destruction. Instead, the macrophage presents the attached antigen to the helper/inducer T-cell. Then, the helper/inducer T-cell and the macrophage together process the antigen to expose the antigen's recognition sites (universal product code). After processing the antigen, the helper/inducer T-cell brings the antigen into contact with the B-cell so that the B-cell can recognize the antigen as non-self.

Sensitization occurs when the B-cell recognizes the antigen as non-self and is now "sensitized" to this antigen. A single unsensitized B-cell can become sensitized only once. So, each B-cell can be sensitized to only one type of antigen.

FIG. 19-9 Antibody structure and the Fc receptors on leukocytes.

Sensitizing allows this B-cell to respond to any substance that carries the same antigens (codes) as the original antigen. The sensitized B-cell always remains sensitized to that specific antigen. In addition, all cells produced by that sensitized B-cell also are already pre-sensitized to that same specific antigen.

Immediately after it is sensitized, the B-cell divides and forms two types of B-lymphocytes, each one remaining sensitized to that specific antigen (see Fig. 19-7). One new cell becomes a **plasma cell**, which starts immediately to produce antibodies against the sensitizing antigen. The other new cell becomes a memory cell. The **memory cell** is a sensitized B-cell but does not start to function until the next exposure to the same antigen (see discussion of *sustained immunity* [memory] on p. 312).

Antibody production and release allow the antibodies to search out specific antigens. Antibodies are produced by plasma cells. When fully stimulated, each plasma cell can make as many as 300 molecules of antibody per second. Each plasma cell produces antibody specific only to the antigen that originally sensitized the parent B-cell. For example, in the case of the baby-sitter who was exposed to and invaded by the chickenpox virus, the plasma cells from those B-cells sensitized to the chickenpox virus can make only anti-chickenpox antibodies. The antibody class (e.g., immunoglobulin G [IgG] or immunoglobulin M [IgM]) that the plasma cell produces may vary, but the antibody can be forever directed only against the chickenpox virus.

Antibody molecules made by plasma cells are released into the blood and other body fluids as free antibody. Each free antibody molecule remains in the blood for 3 to 30 days. Because the antibody is in body fluids (or body “humors”) and is separate from the B-cells, this type of immunity is sometimes called **humoral immunity** (Kaufman, 2011). *Circulating antibodies can be transferred from one person to another to provide the receiving person with immediate immunity of short duration.*

Antibody-antigen binding is needed for anti-antigen actions. Antibodies are Y-shaped molecules (Fig. 19-9). The tips of the short arms of the Y recognize the specific antigen

FIG. 19-10 Formation of large and small antigen-antibody complexes (immune complexes).

and bind to it. Because each antibody molecule has two tips (Fab fragments, or arms), each antibody can bind either to two separate antigens or to two areas of the same antigen.

The stem of the Y is the “Fc fragment.” This area can bind to Fc receptor sites on white blood cells (WBCs). The WBC then not only has its own means of attacking antigens but also has the added power of having surface antibodies that can stick to antigens (see Fig. 19-9).

The binding of antibody to antigen may not be lethal to the antigen. Instead, antibody-antigen binding starts other actions that neutralize, eliminate, or destroy the antigen.

Antibody-binding actions are triggered by binding of antibody to antigen. The resulting reactions neutralize, eliminate, or destroy the bound antigen. These actions include agglutination, lysis, complement fixation, precipitation, and inactivation or neutralization.

Agglutination is a clumping action that results from the antibody linking antigens together, forming large and small immune complexes (Fig. 19-10). Agglutination alone does not directly destroy the antigen, but it starts other defensive effects. It slows the movement of the antigen in body fluids. Also, the irregular shape of the antigen-antibody complex (see Fig. 19-10) allows that complex to be attacked more easily by macrophages and neutrophils.

Lysis is cell membrane destruction, and it occurs now because of antibody binding to membrane-bound antigens of some invaders. The actual binding makes holes in the invader’s membrane, weakening the invader. This response usually requires that complement be activated and “fixed” to the immune complex. Bacteria and viruses are the non-self cells that are damaged most through lysis caused by the binding of antibody to antigens.

Complement activation and fixation are actions triggered by some classes of antibodies that can remove or destroy antigen. (See discussion of *adherence* on p. 308 for an explanation of how complement assists in immunity.) The two classes of antibody that can activate the complement system are IgG and IgM. Binding of antibody from either of these classes to antigen provides a binding site for the first component of complement. Once the first complement molecule is activated, other proteins of the complement system are activated in a cascade.

Precipitation is similar to agglutination but has a larger response. With precipitation, antibody molecules bind so much antigen that large antigen-antibody complexes are formed. These complexes cannot stay in suspension in the blood. Instead, they form a large precipitate, which then can be acted on and removed by neutrophils and macrophages.

Inactivation (neutralization) is the process of making an antigen harmless without destroying it. Usually only a small area of the antigen, the active site, causes the harmful effects. The rest of the antigen may not be harmful to the host. When an antibody binds to an antigen and covers up the antigen's active site, the antigen is made harmless without destroying it.

Sustained immunity (memory) provides us with long-lasting immunity to a specific antigen. Sustained immunity results from memory B-cells made during the lymphocyte sensitization stage. These memory cells remain sensitized to the specific antigen to which they were originally exposed. On re-exposure to the same antigen, the memory cells rapidly respond by first dividing and forming new sensitized blast cells and plasma cells. The blast cells continue to divide, producing many more sensitized plasma cells. These new sensitized plasma cells rapidly make large amounts of the antibody specific for the sensitizing antigen.

This ability of the memory cells to respond on re-exposure to the same antigen that originally sensitized the B-cell allows a rapid and large immune (*anamnestic*) response to the antigen. Because so much antibody is made, often the invading organisms are removed completely and the person does not become ill. This process prevents people from becoming ill with chickenpox or any infectious disease more than once, even though they are exposed many times to the causative organism. Without immunologic memory, people would remain susceptible to specific diseases on subsequent exposure to the organisms and no long-term immunity would be generated (Abbas et al., 2010; McCance et al., 2010).

Antibody Classification

All antibodies are immunoglobulins, also called *gamma globulins*. These names are based on the structure and function of antibodies. A globulin is a protein that is globular rather than straight. Because antibodies are globular proteins, they are "globulins." The term **immunoglobulin** is used for antibodies because they are globular proteins that provide immunity. Antibodies also are called **gamma globulins** because all free antibodies in the plasma separate out in the gamma fraction of plasma proteins during electrophoresis. The five antibody types are classified by differences in size, location, amount, function, and timing (Table 19-4).

On first exposure to an antigen, the newly sensitized B-cell produces the IgM antibody type against the antigen. IgM is special because it forms itself into a five-member group. Each IgM group, then, has ten antigen binding sites. So, even though antibody production is slow on first exposure, the antibody type produced forms groups that are very efficient at antigen binding. This process ensures that the initial illness, like chickenpox, lasts only 5 to 10 days. On re-exposure to the same antigen, the already sensitized B-cell makes large amounts of the IgG type of antibody against that antigen. Although IgG does not form groups of five, the enormous amounts produced make IgG antibodies efficient at clearing the antigen and protecting the person from becoming ill with the disease again.

TABLE 19-4 ANTIBODY CLASSIFICATION

ANTIBODY	FUNCTION
IgA	"Secretory" antibody that forms a dimeric (two antibody group) structure Present in high concentrations in the secretions of mucous membranes and in the intestinal mucosa Very low circulating levels Most responsible for preventing infection in the upper and lower respiratory tracts, the GI tract, and the genitourinary tract
IgD	Present in low blood concentrations Co-expressed with IgM Acts as a receptor on unsensitized B-lymphocytes
IgE	Variable concentration in blood Associated with antibody-mediated hypersensitivity reactions Binds to mast cells and causes their degranulation when an allergen (antigen) binds to IgE antigen recognition sites
IgG	Composes at least 75% of circulating antibody population Is heavily expressed on second and subsequent exposures to antigens Is greatly responsible for providing sustained, long-term immunity against invading microorganisms Activates classic complement pathway, enhancing effectiveness of neutrophil and macrophage phagocytosis Involved in the antibody-dependent cell-mediated non-self cell killing action of natural killer cells
IgM	First antibody formed by a newly sensitized B-lymphocyte plasma cell Composes about 10% to 15% of circulating antibody population Especially effective at the antibody actions of agglutination and precipitation Largest antibody molecule forming a pentameric (five antibody group) structure with 10 potential binding sites Activates classic complement pathway

Acquiring Antibody-Mediated Immunity

Antibody-mediated immunity (AMI) is one type of adaptive immunity. **Adaptive immunity** is the immunity that a person's body learns to make (or can receive) as an adaptive response to invasion by organisms or foreign proteins. For example, antibody-mediated immunity is an acquired immunity. Adaptive immunity occurs either naturally or artificially through lymphocyte responses and can be either active or passive.

Active immunity occurs when antigens enter the body and the body responds by making specific antibodies against the antigen. This type of immunity is *active* because the body takes an active part in making antibodies. Active immunity occurs under natural or artificial conditions.

Natural active immunity occurs when an antigen enters the body without human assistance and the body responds by actively making antibodies against that antigen (e.g., chickenpox virus). Usually, the invasion that triggers antibody production also causes the disease. However, processes occurring in the body at the same time as infection create immunity to that antigen. Thus the person will not become ill after a second exposure to the same antigen. *This type of*

immunity is the most effective and the longest lasting (Abbas et al., 2010; McCance et al., 2010).

Artificial active immunity is the protection developed by vaccination or immunization. This type of immunity is used to prevent infections or illnesses (e.g., tetanus, diphtheria, polio) that have such serious consequences that avoiding the disease altogether is most desirable. Small amounts of specific antigens are placed as a vaccination into a person. The person's immune system responds by actively making antibodies against the antigen. Because antigens used for this procedure have been specially processed to make them less likely to grow in the body (**attenuated**), this exposure does not cause the disease. Artificial active immunity lasts many years, although repeated but smaller doses of the original antigen are required as a "booster" to retain the protection.

Passive immunity occurs when antibodies against an antigen are in a person's body but were not created there. Rather, these antibodies are transferred to the person's body after being made in the body of another person or animal. Because these antibodies are foreign to the receiving person, they are recognized as non-self and eliminated quickly. For this reason, passive immunity provides only immediate, short-term protection against a specific antigen.

Natural passive immunity occurs when antibodies are passed from the mother to the fetus via the placenta or to the infant through colostrum and breast milk.

Artificial passive immunity involves injecting a person with antibodies that were produced in another person or animal. This type of immunity is used when a person is exposed to a serious disease for which he or she has little or no actively acquired immunity. Instead, the injected antibodies are expected to inactivate the antigen. This type of immune protection is temporary, lasting only days to a few weeks. Artificial passive immunity may be used to prevent disease or death for patients exposed to rabies, tetanus, and poisonous snake bites.

AMI works with inflammation to protect against infection. However, AMI can provide the most effective long-lasting immunity only when its actions are combined with those of cell-mediated immunity.

Cell-Mediated Immunity

Cell-mediated immunity (CMI), or cellular immunity, involves many white blood cell (WBC) actions and interactions. This type of immunity, which is another type of adaptive or acquired true immunity, is provided by lymphocyte stem cells that mature in the secondary lymphoid tissues of the thymus and pericortical areas of lymph nodes (see Fig. 19-7). Certain CMI responses influence and regulate the activities of antibody-mediated immunity (AMI) and inflammation by producing and releasing cytokines. For total immunocompetence, then, CMI must function optimally.

Cell Types Involved in Cell-Mediated Immunity

The WBCs with the most important roles in CMI include several specific T-lymphocytes (T-cells) along with a special population of cells known as *natural killer (NK) cells*. T-cells have a variety of subsets, each of which has a specific function.

One way of identifying different T-cell subsets is to examine certain "marker proteins" (antigens) on the cell

membrane's surface. More than 200 different T-cell proteins have been identified on the cell membrane, and some of these are commonly used clinically to identify specific cells (Abbas et al., 2010). Antibodies have been made against each of these proteins. Thus each T-cell subset can be identified by its reaction to the commercial antibodies. Most T-cells have more than one antigen on their cell membrane. For example, all mature T-cells contain T1, T3, T10, and T11 proteins. Most T-cells also contain specific T-cell membrane antigens.

The names used to identify specific T-cell subsets include the specific membrane antigen and the overall actions of the cells in a subset. The three T-lymphocyte subsets that are critically important for the development and continuation of CMI are helper/inducer T-cells, suppressor T-cells, and cytotoxic/cytolytic T-cells. An additional cell, the natural killer cell, although not a true T-cell, also contributes to CMI.

Helper/inducer T-cells have the T4 protein on their membranes. These cells are usually called *T4+ cells* or *T_H cells*. The most correct name for helper/inducer T-cells is *CD4+* (cluster of differentiation 4). Formerly, T4 cells have been referred to as cells that are *OKT4 positive* or *Leu-3 positive* because of the specific antigens on their membrane surfaces.

Helper/inducer T-cells easily recognize self cells versus non-self cells. In response to the recognition of non-self (antigen), helper/inducer T-cells secrete lymphokines that can enhance the activity of other WBCs.

Most lymphokines secreted by the helper/inducer T-cells increase immune function. These lymphokines increase bone marrow production of stem cells and speed up their maturation. Thus helper/inducer T-cells act as organizers in "calling to arms" various squads of WBCs involved in inflammatory, antibody, and cellular protective actions to destroy or neutralize antigens.

Suppressor T-cells have the T8-lymphocyte antigen on membrane surfaces. These cells are commonly called *T8+ cells*, *CD8+ cells*, or *T_S-cells*. Suppressor T-cells help regulate CMI.

Suppressor T-cells prevent **hypersensitivity** (immune overreactions) on exposure to non-self cells or proteins. This function is important in preventing the formation of antibodies directed against normal, healthy self cells, which is the basis for many autoimmune diseases (McCance et al., 2010).

The suppressor T-cells secrete lymphokines that have an overall *inhibitory* action on most cells of the immune system. These lymphokines inhibit both the growth and activation of immune system cells.

Suppressor T-cells have the opposite action of helper/inducer T-cells. For optimal function of CMI, then, a balance between helper/inducer T-cell activity and suppressor T-cell activity must be maintained. This balance occurs when the helper/inducer T-cells outnumber the suppressor T-cells by a ratio of 2:1. When this ratio increases, indicating that helper/inducer T-cells vastly outnumber the suppressor cells, overreactions can occur, some of which are tissue damaging as well as unpleasant. When the helper-suppressor ratio decreases, indicating fewer-than-normal helper/inducer T-cells, immune function is suppressed and the person's risk for infections increases.

Cytotoxic/cytolytic T-cells are also called *T_C-cells*. Because they have the T8 protein present on their surfaces, they are a subset of suppressor cells. Cytotoxic/cytolytic T-cells destroy cells that contain a processed antigen's human

leukocyte antigens (HLAs). This activity is most effective against self cells infected by parasites, such as viruses or protozoa.

Parasite-infected self cells have both self HLA proteins (universal product code) and the parasite's antigens on the cell surface. This allows the person's immune system cells to recognize the infected self cell as abnormal, and the cytotoxic/cytolytic T-cell can bind to it.

When the cytotoxic/cytolytic T-cell binds to the infected cell's HLAs, the cytotoxic/cytolytic T-cell makes holes in the membrane of the infected cell and delivers a "lethal hit" of enzymes to the infected cell, causing it to lyse and die. Once the lethal hit has been delivered to the infected cell, the cytotoxic/cytolytic T-cell releases the dying infected cell and can then attack and destroy other infected cells that express the same antigen HLAs.

Natural killer (NK) cells are also known as *CD16+ cells* and are very important in providing CMI. The actual site of NK cell differentiation and maturation is unknown. Although this cell type has some T-cell features, it is not a true T-cell subset (Abbas et al., 2010).

NK cells have direct cytotoxic effects on some non-self cells without first being sensitized. These killing actions of NK cells are in addition to the interactions of other WBCs. NK cells conduct "seek and destroy" missions in the body to eliminate non-self cells.

NK cells are most effective in destroying unhealthy or abnormal self cells. The non-self cells most often harmed by NK cells are cancer cells and virally infected body cells.

Cytokines

Cell-mediated immunity (CMI) regulates the immune system by the production and activity of cytokines. **Cytokines** are small protein hormones produced by the many WBCs (and some other tissues). Cytokines made by the macrophages, neutrophils, eosinophils, and monocytes are called **monokines**. Cytokines produced by T-cells are called **lymphokines**.

Cytokines work like hormones: one cell produces a cytokine, which in turn exerts its effects on other cells of the immune system and on other body cells. The cells responding to the cytokine may be located close to or remote from the cytokine-secreting cell. Thus cytokines act like "messengers" that tell specific cells how and when to respond. The cells that change their activity when a cytokine is present are "responder" cells. For a responder cell to respond to the presence of a cytokine, the responder cell must have a specific receptor to which the cytokine can bind. Once the cytokine binds to its receptor, the responder cell changes its activity.

Cytokines control many inflammatory and immune responses and are controlled by interactions with other systems, especially the nervous system. Some cytokines are *pleiotropic* (their effects are widespread within the immune system) and set into motion many different immune actions. Other cytokines have specific actions limited to only one type of cell. Cytokines include the interleukins, interferons, colony-stimulating factors, and tumor necrosis factor. The interleukins are the largest group of cytokines, with interleukin-33 (IL-33) being the most recently defined. Although there are many cytokines, not all are clinically useful at this time; however, this is an area of continuing research and discovery. Table 19-5 lists the cytokines that have current clinical

TABLE 19-5 ACTIVITY OF SELECTED CYTOKINES

CYTOKINE	ACTIONS
Pro-inflammatory Cytokines	
Interleukin-1 (IL-1)	Induces fever Stimulates production of prostaglandins Increases growth of CD4+ T-cells
Interleukin-2 (IL-2)	Increases growth and differentiation of T-lymphocytes Enhances natural killer cell activity against cancer cells
Interleukin-6 (IL-6)	Stimulates liver to produce fibrinogen and protein C Increases rate of bone marrow production of stem cells Increases numbers of sensitized B-lymphocytes
Tumor Necrosis Factor (TNF)	Induces fever Major cytokine involved in rheumatoid arthritis damage Major cytokine involved in the acute inflammatory response to infectious bacteria and starts many of the systemic complications of severe infection or sepsis Increases leukocyte adhesion Participates in graft rejection Induces cachexia and muscle breakdown Induces cell death Stimulates delayed hypersensitivity reactions and allergy
Growth Factors	
Granulocyte Colony-Stimulating Factor (G-CSF)	Increases numbers and maturity of neutrophils
Granulocyte-Macrophage Colony-Stimulating Factor (GM-CSF)	Increases growth and maturation of myeloid stem cells
Erythropoietin	Increases growth and differentiation of erythrocytes
Thrombopoietin	Increases growth and differentiation of platelets

importance. Chapters discussing specific diseases (e.g., lymphoma, rheumatoid arthritis) caused by or treated with certain cytokines have more information about the role of specific cytokines in the disease and its treatment.

Protection Provided by Cell-Mediated Immunity

Cell-mediated immunity (CMI) helps protect the body through the ability to differentiate self from non-self. The non-self cells most easily recognized by CMI are cancer cells and those self cells infected by organisms that live within host cells. CMI watches for and rids the body of self cells that might potentially harm the body. *CMI is important in preventing the development of cancer and metastasis after exposure to carcinogens.*

Transplant Rejection

Natural killer (NK) cells and cytotoxic/cytolytic T-cells also destroy cells from other people or animals. Although this action is normal and is usually helpful, it is also responsible

for rejection of tissue grafts and transplanted organs (also termed *grafts*). Because the solid organ transplanted into the recipient is seldom a perfectly identical match of human leukocyte antigens (unless the organ is obtained from an identical sibling) between the donated organ and the recipient host, the patient's immune system cells recognize a newly transplanted organ as non-self. Without intervention, the recipient's immune system starts inflammatory and immunologic actions to destroy or eliminate these non-self cells. This activity causes rejection of the transplanted organ. Rejection of transplanted solid organs and other grafts is a result of a complex series of responses that change over time and involve different components of the immune system. Rejection can be hyperacute, acute, or chronic.

Hyperacute Rejection

Hyperacute rejection begins immediately on transplantation and is an antibody-mediated response. Antigen-antibody complexes form in the blood vessels of the transplanted organ. The recipient's (host's) blood has pre-existing antibodies to one or more of the antigens (including blood group antigens) present in the donated organ. The antigen-antibody complexes adhere to the lining of blood vessels and activate complement. The activated complement in the blood vessel linings triggers the blood clotting cascade, causing small clots to form throughout the new organ. Widespread clotting occludes blood vessels and leads to ischemic necrosis, inflammation with phagocytosis of the necrotic blood vessels, and release of lytic enzymes into the new organ. These enzymes cause massive cellular destruction within the transplanted organ and graft loss.

Hyperacute rejection occurs mostly in transplanted kidneys but is less common now as a result of greater efforts in HLA matching. The patients at greatest risk for hyperacute rejection are those who have received donated organs of an ABO blood type different from their own, have received multiple blood transfusions at any time in life before transplantation, have a history of multiple pregnancies, or have received a previous transplant.

The manifestations of hyperacute rejection are apparent within minutes of attachment of the donated organ to the recipient's blood supply. The process cannot be stopped once it has started, and the rejected organ is removed as soon as hyperacute rejection is diagnosed.

Acute Rejection

Acute rejection first occurs within 1 week to 3 months after transplantation and may occur sporadically after that. Two mechanisms are responsible. The first mechanism is antibody mediated and results in vasculitis within the transplanted organ. This reaction differs from hyperacute rejection in that blood vessel necrosis (not occlusion) leads to organ destruction.

The second mechanism is cellular. The recipient's cytotoxic/cytolytic T-cells and NK cells enter the transplanted organ through the blood, penetrate the organ cells, start an inflammatory response, and cause lysis of the organ cells (Abbas et al., 2010).

Diagnosis of acute rejection is made by laboratory tests that show impaired function of the donated organ and by biopsy of the donated organ. Symptoms of acute rejection vary with each patient and with the specific organ

transplanted. For example, when acute rejection occurs in a transplanted kidney, the patient usually has some tenderness in the kidney area and may have other general symptoms of inflammation.

An episode of acute rejection after solid organ transplantation does not automatically mean that the patient will lose the new organ. Drug management of the recipient's immune responses at this time may limit the damage to the organ and allow the graft to be maintained.

Chronic Rejection

The origin of *chronic rejection* is not clear, but it is similar to chronic inflammation and scarring. The smooth muscles of blood vessels overgrow and occlude the vessels. The donated organ tissues are replaced with fibrotic, scarlike tissue. Because this fibrotic tissue is not organ tissue, the transplanted organ's function is reduced in proportion to the amount of normal tissue that is replaced by fibrotic tissue. This type of reaction is long-standing and occurs continuously as a response to chronic ischemia caused by blood vessel injury. The results of chronic rejection are unique to different transplanted organs. For example, in transplanted lungs, chronic rejection thickens small airways. In transplanted livers, chronic rejection destroys bile ducts. In transplanted hearts, this process is called *accelerated graft atherosclerosis (AGA)* and is the major cause of death in patients who have survived 1 or more years after heart transplantation.

Although good control over the recipient's immune function can delay this type of rejection, the process probably occurs to some degree with all transplanted solid organs obtained from donors who are not identical siblings of the recipients. Because the fibrotic changes are permanent, there is no cure for chronic graft rejection. When the fibrosis increases to the extent that the transplanted organ can no longer function, the only recourse is retransplantation.

Management of Transplant Rejection

Rejection of transplanted solid organs involves all three components of immunity, although cell-mediated immune (CMI) responses contribute the most to the rejection process.

Maintenance therapy is the continuous immunosuppression used after a solid organ transplant. The drugs used for routine therapy after solid organ transplantation are combinations of specific immunosuppressants (cyclosporine [Sandimmune, Neoral, Gengraf]); less specific immunosuppressants (azathioprine [Imuran] or mycophenolate [CellCept, Myfortic]); and one of the corticosteroids, such as prednisone (Apo-Prednisone, Deltasone) or prednisolone (Delta-Cortef). Cyclosporine induces the specific and effective suppression of rejection. This drug, however, induces major long-term adverse actions and is expensive. A new similar drug under investigation is gusperimus (Spanidin). The dosage of all immunosuppressive agents is adjusted to the immune response of each patient. Treatment with these agents increases the risk for bacterial and fungal infections and for cancer development.

Tacrolimus (Prograf) is similar to erythromycin and specifically suppresses T-cell actions, including production of interleukin-2 (IL-2). These effects occur through several mechanisms. Without continuous stimulation by IL-2, helper/inducer T-cells and cytotoxic/cytolytic T-cells are slow to reproduce and do not perform their usual functions.

Suppression of these two cell populations allows the donated organ to remain free from immunologic destruction. The general immunosuppression is not as profound, and the patient's risk for infection is not greatly increased. Tacrolimus also prevents activation of unsensitized cytotoxic/cytolytic T-cells. Other drugs with similar actions include sirolimus (Rapamune) and the investigational drug everolimus (Certican).

Another approach to prevent transplant rejection for patients undergoing kidney transplantation is the use of monoclonal antibodies directed against the IL-2 receptor site on activated T-cells (especially helper/inducer T-cells). These antibodies, basiliximab (Simulect) or daclizumab (Zenapax), are given IV within 2 hours before the transplant surgery and within the first few days after the surgery. By binding the antibodies to the IL-2 receptor site, T-cell growth and activation are reduced for several months.

A drug used as cancer therapy, bortezomib (Velcade), is under investigation as a potential antirejection drug for kidney transplant. It is a proteasome inhibitor that works by inhibiting a large complex of proteins in cell fluid (cytoplasm) that regulate the expression of substances that promote cell division. This drug appears to work against transplant rejection by causing immunosuppression and possibly by reducing scar tissue formation stimulated by inflammatory responses.

Rescue therapy is used to treat acute rejection episodes. These agents may be used in addition to or in place of the maintenance drugs in the patient's normal treatment regimen.

Antilymphocyte globulin (ALG) is an antibody (or group of antibodies) produced in an animal (e.g., mouse, horse, rabbit) after the animal has been exposed to human

lymphocytes. The globulin can be made more specific by exposing the animal to human T-cells instead of mixed lymphocytes. When these antihuman lymphocyte antibodies are given to humans, the antibodies selectively attack and clear lymphocytes from body fluids, blood, and the transplanted organ. These agents are given only for a short time to combat the acute rejection episode because of the immunologic side effects, ranging from low-grade fever and malaise to serum sickness and anaphylaxis. The side effects usually increase in intensity on repeated exposure to ALG.

Muromonab-CD3 (OKT3) is an antibody directed specifically against the human T-cell cell-surface antigen CD3. This antibody is generated in mice rather than in horses. Because the agent is generated in mice, the patients receiving it rapidly develop antimouse antibodies. These antimouse antibodies attack the CD3 and prevent its anti-T-cell activities. This antibody is most effective against rejection during the first episode in which it is used. Its effectiveness in combating graft rejection decreases with each use. Like ALG, this drug is given only for a short time to combat the acute rejection episode because of the immunologic side effects, which increase in intensity on repeated exposure.

Antibodies made in other animals, especially mice, cause side effects in humans because the animal proteins in the antibodies are recognized as foreign by the human immune system. The incidence of side effects is decreasing because newer antibodies have been "humanized." This process removes most of the mouse-specific proteins from the antibody and replaces them with human-specific proteins. Many humanized antibodies made by mice now contain up to 95% human proteins rather than mouse proteins and some are fully humanized, containing no mouse proteins.

KEY POINTS

Review these Key Points for each NCLEX Examination Client Needs Category.

Physiological Integrity

- Inflammation and immunity are provided through the actions and products of white blood cells (WBCs), also called *leukocytes*.
- Different types of WBCs provide different types of immune or inflammatory protection.
- The differential of the WBC count can be used to determine the patient's risk for infection, the presence or absence of infection, the presence or absence of an allergic reaction, and whether an infection is bacterial or viral.
- WBCs are the only body cells able to recognize non-self cells and to attack them.
- Self-tolerance is the special ability of WBCs to recognize healthy self cells and not attempt to attack or destroy them.
- Human leukocyte antigens (HLAs) are a person's tissue type and are inherited from parents.
- Immunocompetence requires that all three parts of inflammation and immunity have optimal functioning.
- Inflammation is a general, nonspecific protective response.

- The five cardinal manifestations of inflammation are redness, warmth, swelling, pain, and loss of function.
- Inflammation and infection are not the same thing. Infection almost always is accompanied by inflammation, but inflammation often occurs without infection.
- The tissue responses to inflammation are helpful if confined to the area of invasion or infection and do not extend beyond the acute phase.
- Chronic inflammation can damage tissues and reduce function.
- The cells and actions of cell-mediated immunity control and coordinate the entire inflammatory and immune responses.
- Inflammatory protection cannot be transferred from one person to another.
- Immune function declines with age, making the older adult at increased risk for infection and cancer development.
- Antibody-mediated immunity (also known as *humoral immunity*) can be transferred from one person or animal to another.

GET READY FOR THE NCLEX® EXAMINATION! —cont'd

- Antibodies transferred from one person into another person have a short-term effect.
- Natural, active immunity is the most beneficial and long-lasting type of immunity.
- Vaccinations cause artificial active immunity and require “boosting” for best long-term effects.
- A person’s normal membrane proteins would be antigens in another person.
- Transplant rejection is a normal response of the immune system that can damage or destroy the transplanted organ.
- Patients who receive transplanted organs (unless from an identical sibling) need to take immunosuppressive drugs daily to prevent transplant rejection.
- Patients who take immunosuppressive drugs have an increased risk for infection and cancer development.

CHAPTER

20

Care of Patients with Arthritis and Other Connective Tissue Diseases

Key Points

Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Collaborate with members of the health care team when providing care to patients with arthritis or other connective tissue disease (CTD).
2. Prioritize collaborative interventions for patients with osteoarthritis (OA) and rheumatoid arthritis (RA).

Health Promotion and Maintenance

3. Identify community resources to help patients achieve or maintain independence in ADLs.
4. Identify risk factors for the development of arthritis and other CTDs.
5. Teach patients how to protect and exercise their joints and conserve their energy.
6. Teach patients how to prevent Lyme disease and detect it early if it occurs.

Psychosocial Integrity

7. Assess the patient's and family's response to arthritis or other CTD, their support systems, and available resources.
8. Assess the patient's and family's sources of stress and coping mechanisms when living with arthritis or other CTD.

Physiological Integrity

9. Compare and contrast the pathophysiology and clinical manifestations of OA and RA.

10. Interpret laboratory findings for patients with RA and other autoimmune CTDs.
11. Apply knowledge of pathophysiology to monitor for and prevent complications of total hip and knee arthroplasty.
12. Teach patients and their families about the postoperative care required after a total joint arthroplasty.
13. Provide information for patients and families about the use and side effects of drug therapy for arthritis or other CTD.
14. Identify the nursing implications associated with drug therapy for patients with rheumatoid arthritis and other CTDs.
15. Evaluate and document patient response to drug therapy.
16. Differentiate between discoid lupus erythematosus and systemic lupus erythematosus.
17. Prioritize nursing interventions for patients who have systemic sclerosis.
18. Describe the patient-centered collaborative care of gout based on knowledge of pathophysiology.
19. Explain the differences between polymyositis, systemic necrotizing vasculitis, polymyalgia rheumatica, ankylosing spondylitis, Reiter's syndrome, and Sjögren's syndrome.
20. Describe current treatment strategies for patients with fibromyalgia syndrome and psoriatic arthritis.

Connective tissue disease (CTD) is the major focus of *rheumatology*, the study of rheumatic disease. A **rheumatic disease** is any disease or condition involving the musculoskeletal system. In this text, CTDs are discussed separately from other musculoskeletal conditions because most CTDs are classified as autoimmune disorders. In autoimmune disease, antibodies attack healthy normal cells and tissues. For reasons that are unclear, the immune system does not recognize body cells as self and therefore triggers an immune response. The usual *protective* nature of the immune system does not function properly in patients with autoimmune CTDs.

Most common CTDs are characterized by chronic pain and progressive joint deterioration, which results in decreased function. Some of these disorders have additional localized clinical manifestations, whereas others are systemic. The economic and social costs of these diseases are staggering and will increase steadily as “baby boomers” continue to age. Patient care usually requires an interdisciplinary approach, including medicine, surgery, nursing, rehabilitation therapy, and/or case management.

More than 46 million people in the United States have at least one of more than 100 types of CTDs, or “arthritis.” **Arthritis** means inflammation of one or more joints. In clinical practice, however, arthritis is categorized as either noninflammatory or inflammatory. Noninflammatory, localized arthritis such as osteoarthritis (OA) is not systemic; OA is not an autoimmune disease. Systemic autoimmune diseases such as rheumatoid arthritis (RA) and systemic lupus erythematosus (SLE) are inflammatory disorders.

OSTEOARTHRITIS

Pathophysiology

Osteoarthritis is the most common arthritis and a major cause of disability among adults in the United States and the world. It is sometimes called *osteoarthrosis* or *degenerative joint disease (DJD)*.

Osteoarthritis is the progressive deterioration and loss of cartilage in one or more joints (articular cartilage). Articular cartilage, also known as *hyaline cartilage*, contains 65% to 80% water. The remaining components form a matrix of:

- Proteoglycans (glycoproteins containing chondroitin, keratin sulfate, and other substances)
- Collagen (elastic substance)
- Chondrocytes (cartilage-forming cells)

As people age or experience joint trauma, proteoglycans decrease. The production of synovial fluid, which provides joint lubrication and nutrition, also declines because of the decreased synthesis of hyaluronic acid and less body fluid in the older adult.

In patients of any age with OA, enzymes, such as stromelysin, break down the articular matrix. In early disease, the cartilage changes from its normal bluish white, translucent color to an opaque and yellowish brown appearance. As cartilage and the bone beneath the cartilage begin to erode, the joint space narrows and **osteophytes** (bone spurs) form (Fig. 20-1). As the disease progresses, fissures, calcifications, and ulcerations develop and the cartilage thins. Inflammatory cytokines (enzymes) such as interleukin-1 (IL-1) enhance this deterioration. The body’s normal repair process cannot

FIG. 20-1 Joint changes in degenerative joint disease.

overcome the rapid process of degeneration (McCance et al., 2010).

Eventually the cartilage disintegrates and pieces of bone and cartilage “float” in the diseased joint causing **crepitus**, a grating sound caused by the loosened bone and cartilage. The resulting joint pain and stiffness can lead to decreased mobility and muscle atrophy. Muscle tissue helps support joints, particularly those that bear weight (e.g., hips, knees).

Etiology and Genetic Risk

The cause of OA is a combination of many factors. For patients with *primary* OA, the disease may be triggered by aging, genetic changes, obesity, and/or smoking. Weight-bearing joints (hips and knees), the vertebral column, and the hands are most commonly affected, probably because they are used most often or bear the mechanical stress of body weight and many years of use.

GENETIC/GENOMIC CONSIDERATIONS

Some patients report a family history of OA, which supports a possible genetic cause, especially for women. Genetic changes may contribute to cartilage destruction, osteophyte formation, or the inability of the cartilage to repair itself.

A classic study reported by Sunk et al. (2007) found a specific genetic link in OA of the knee. They reported that an increase in *discoidin domain receptor 2 (DDR-2)* expression in diseased joint cartilage was correlated with the degree of tissue damage. The authors concluded that this change occurs after the decrease in proteoglycans from aging. Studies are being conducted to further explore the genetic factors related to OA.

Other factors that can lead to OA are obesity and smoking. Obesity causes joint degeneration, particularly in the knees. Smoking leads to knee cartilage loss, especially in patients with a family history of knee OA. This finding shows a gene-environment interaction in the cause of knee OA (Ding et al., 2007).

Secondary OA occurs less often than primary disease and can result from other musculoskeletal conditions, such as rheumatoid arthritis. Trauma to the joints from excessive use or abuse also predisposes a person to OA. Certain heavy manual occupations (e.g., carpet laying, construction, farming) cause high-intensity or repetitive stress to the joints.

The risk for hip and knee OA is also increased in professional athletes, especially football players, runners, and gymnasts.

In a small percentage of people, congenital anomalies, trauma, and joint sepsis can result in *secondary* OA. For example, injuries or joint surgeries resulting from motor vehicle crashes or falls can cause OA in later years. Certain metabolic diseases (e.g., diabetes mellitus, Paget's disease of the bone) and blood disorders (e.g., hemophilia, sickle cell disease) can also cause joint degeneration.

Incidence and Prevalence

The prevalence of OA varies among different populations but is a universal problem. Most people older than 60 years have joint changes that can be seen on x-ray examination, although not all of those people actually develop the disease. According to Arthritis Foundation estimates, 16 million women older than 40 years have OA compared with 11 million men. Although the cause for this difference is not known, a contributing factor is probably obesity. As women age and have children, they tend to gain more weight than men.

Health Promotion and Maintenance

Based on the contributing factors for OA development, several lifestyle changes can help prevent or slow joint degeneration. These practices include:

- Keep body weight within normal limits; obesity causes excess wear on joints, especially hips and knees.
- Stop or do not start smoking.
- Avoid or limit activities that promote stress on joints, unless absolutely necessary.
- Limit participation in recreational sports that can damage joints, such as football.
- Wear supportive shoes to prevent falls and damage to foot joints, especially metatarsal joints.
- Do not perform repetitive stress activities, such as knitting or typing, for prolonged periods.
- Avoid risk-taking activities to prevent trauma that can result in OA later in life.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

History

Patients with OA usually seek medical attention in ambulatory care settings for their joint pain. However, you will also care for those who have OA as a secondary diagnosis in acute and chronic care facilities. Ask the patient about the course of the disease. Collect information specifically related to OA, such as the nature and location of joint pain and how much pain he or she is experiencing. *Remember that older patients may underreport pain, resulting in inadequate pain management.* Use a 0-to-10 scale or other assessment tool to assess pain intensity. Chapter 5 discusses pain assessment in detail.

Other questions to ask include:

- If joint stiffness has occurred, where and for how long?
- When and where has any joint swelling occurred?
- What do you do to control the pain or stiffness?
- Do you have any loss of function or difficulty in performing ADLs?

Because this disease occurs more often in older women, age and gender are important factors for the nursing history. Ask patients about their occupation, nature of work, history of trauma or falls, weight history, smoking history, and current or previous involvement in sports, because these are all risk factors for the disease. A history of obesity is significant, even for those currently within the ideal range for body weight. Document any family history of arthritis. Determine whether the patient has a current or previous medical condition that may cause joint symptoms.

Physical Assessment/Clinical Manifestations

In the early stage of the disease, the clinical manifestations of OA may appear similar to those of rheumatoid arthritis (RA). The distinction between OA and RA becomes more evident as the disease progresses. Table 20-1 compares the major characteristics of both diseases and their common drug therapy.

The typical patient with OA is a middle-aged or older woman who reports *chronic joint pain and stiffness*. Early in the course of the disease, the pain diminishes after rest and worsens after activity. Later the pain occurs with slight motion or even when at rest. Because cartilage has no nerve supply, the pain is probably caused by joint and soft-tissue involvement and by spasms of the surrounding muscles. During the joint examination, the patient may have pain or tenderness by palpation or by putting the joint through range of motion. Crepitus may be felt or heard as the joint goes through range of motion. One or more joints may be affected. The patient may also report joint stiffness that usually lasts less than 30 minutes after a period of inactivity.

On inspection, the joint is often enlarged because of bony hypertrophy. The joint feels hard on palpation. Although not common, the presence of inflammation in patients with OA indicates a secondary synovitis. About half of patients with hand involvement have **Heberden's nodes** (at the distal interphalangeal [DIP] joints) and **Bouchard's nodes** (at the proximal interphalangeal [PIP] joints). Although OA is *not* a bilateral, symmetric disease, these large bony nodes appear on both hands, especially in women. The nodes may be painful and red. Some patients experience pain in developing nodes or when nodes are palpated. These deformities tend to be familial and are often a cosmetic concern to patients.

Joint effusions (excess joint fluid) are common when the knees are involved. When trying to differentiate the presence of fluid from subcutaneous tissue, you may be able to move fluid from the **infrapatellar notch** (the area directly below the knee) into the **suprapatellar area** (directly above the knee).

Observe any *atrophy of skeletal muscle* from disuse. The vicious pain cycle of the disease discourages the movement of painful joints, which may result in contractures, muscle atrophy, and further pain. *Loss of function* may result, depending on which joints are involved. Hip or knee pain may cause the patient to limp and restrict walking distance.

Osteoarthritis (OA) can affect the spine, especially the lumbar region at the L3-4 level or the cervical region at C4-6 (neck). Compression of spinal nerve roots may occur as a result of vertebral facet bone spurs. The patient typically reports radiating pain, stiffness, and muscle spasms in one or both extremities.

TABLE 20-1 DIFFERENTIAL FEATURES OF RHEUMATOID ARTHRITIS AND OSTEOARTHRITIS

CHARACTERISTIC	RHEUMATOID ARTHRITIS	OSTEOARTHRITIS
Typical onset (age)	35-45 yr	Older than 60 yr
Gender affected	Female (3:1)	Female (2:1)
Risk factors or cause	Autoimmune (genetic basis) Emotional stress (triggers exacerbation) Environmental factors	Aging Genetic factor (possible) Obesity Trauma Occupation
Disease process	Inflammatory	Degenerative
Disease pattern	Bilateral, symmetric, multiple joints Usually affects upper extremities first Distal interphalangeal joints of hands spared Systemic	May be unilateral, single joint Affects weight-bearing joints and hands, spine Metacarpophalangeal joints spared Nonsystemic
Laboratory findings	Elevated rheumatoid factor, antinuclear antibody, ESR	Normal or slightly elevated ESR
Common drug therapy	NSAIDs (short-term use) Methotrexate Leflunomide (Arava) Corticosteroids Biological response modifiers Other immunosuppressive agents	NSAIDs (short-term use) Acetaminophen Other analgesics

ESR, Erythrocyte sedimentation rate; NSAIDs, nonsteroidal anti-inflammatory drugs.

Severe pain and deformity interfere with ambulation and self-care. In addition to performing a musculoskeletal assessment, collaborate with the physical and occupational therapists to conduct a functional assessment. Assess the patient's mobility and ability to perform ADLs. [Chapter 8](#) describes functional assessment.

Psychosocial Assessment

OA is a chronic condition that may cause permanent changes in lifestyle. An inability to care for oneself in advanced disease can result in role changes and other losses. Constant pain interferes with quality of life. Chronic pain can also affect sexuality. Patients may not have the energy for sexual intercourse or may find positioning uncomfortable ([Gevirtz, 2008](#)).

Patients with continuous pain from arthritis may develop depression or anxiety. The patient may also have a role change in the family, workplace, or both. To identify changes that have been or need to be made, ask his or her roles before the disease developed. Identify coping strategies to help live with the disease. Ask the patient about his or her expectations regarding treatment for OA.

In addition to role changes, joint deformities and bony nodules often alter body image and self-esteem. Observe the patient's response to body changes. Does he or she ignore them or seem overly occupied with them? Ask the patients directly how they perceive their body image. Document your assessment findings in the interdisciplinary health care record per agency policy.

Laboratory Assessment

The health care provider uses the history and physical examination to make the diagnosis of OA. The results of routine laboratory tests are usually normal but can be helpful in screening for associated conditions. The erythrocyte sedimentation rate (ESR) and high-sensitivity C-reactive protein (hsCRP) may be slightly elevated when secondary synovitis

(synovial inflammation) occurs. The ESR also tends to rise with age, infection, and other inflammatory disorders.

Imaging Assessment

Routine x-rays are useful in determining structural joint changes. Specialized views are obtained when the disease cannot be visualized on standard x-ray film but is suspected. Magnetic resonance imaging (MRI) may be used to determine vertebral or knee involvement.

ANALYSIS

The priority problems for patients with osteoarthritis (OA) are:

1. Chronic Pain related to cartilage deterioration
2. Decreased mobility related to joint pain and muscle atrophy

PLANNING AND IMPLEMENTATION

In 2008, the Osteoarthritis Research Society International (OARSI) group published evidence-based expert consensus guidelines for patients with knee and hip OA ([Zhang et al., 2008](#)). These interdisciplinary best practice guidelines have major implications for nursing care and are reflected in the following discussion.

Managing Chronic Pain

Planning: Expected Outcomes. The patient with OA is expected to have pain control that is acceptable to the patient (e.g., at a 3 on a pain intensity scale of 0 to 10).

Interventions. Optimal management of patients with OA requires drug therapy and nonpharmacologic measures. If these measures are ineffective, surgery may be performed to reduce pain ([Zhang et al., 2008](#)). Perform a pain assessment before and after implementing interventions.

Nonsurgical Management. Management of chronic joint pain is difficult for both the patient and the health care

professional. A combination of modalities is often used, including analgesics, rest, positioning, thermal modalities, weight control, and integrative therapies. **Chapter 5** elaborates on methods of pain control for chronic pain.

Drug Therapy. The purpose of drug therapy is to reduce pain caused by cartilage destruction, muscle spasm, and/or secondary joint inflammation. The American Pain Society recommends regular *acetaminophen* (Tylenol, Atasol 🍀) as the primary drug of choice because OA is not a primary anti-inflammatory disorder.

! NURSING SAFETY PRIORITY

Drug Alert

Patients are at risk for liver damage if they take more than 4000 mg daily of acetaminophen, have alcoholism, or have liver disease. Older adults are particularly at risk because of normal changes of aging, such as slowed excretion of drug metabolites. Remind patients to read the labels of over-the-counter (OTC) or prescription drugs that could contain acetaminophen before taking them. Teach them that their liver enzyme levels will be monitored while taking this drug.

Topical drug applications may help with temporary relief of pain. Prescription lidocaine 5% patches (Lidoderm) have been approved by the Federal Drug Administration (FDA) for postherpetic neuralgia (nerve pain) but may also relieve joint pain (especially the knee) for some patients. Teach the patient to apply the patch on clean, intact skin for 12 hours each day. Up to three patches may be applied to painful joints at one time. Remind him or her that Lidoderm can cause skin irritation. Teach the patient that the lidocaine patch is contraindicated in those on class I antidysrhythmics. Topical salicylates, such as OTC Aspercreme patch, gel, or cream, are also useful for some patients as a temporary pain reliever, especially for knee pain.

If acetaminophen or topical agents do not relieve pain, the analgesic drug class of choice may be *nonsteroidal anti-inflammatory drugs (NSAIDs)* if the patient can tolerate them (see **Chart 20-9** later in this chapter). Before beginning NSAID therapy, baseline laboratory information is obtained, including a complete blood count (CBC) and kidney and liver function tests. Celecoxib (Celebrex), a COX-2 inhibitor, is usually the first choice unless the patient has hypertension, renal disease, or cardiovascular disease.

! NURSING SAFETY PRIORITY

Drug Alert

All of the COX-2 inhibiting drugs are thought to cause cardiovascular disease, such as myocardial infarction, and renal problems. All of these drugs may be unavailable at some time in the future. Older NSAIDs, such as ibuprofen, can cause severe GI side effects, bleeding, and acute renal failure. Teach your patient about adverse effects from NSAIDs and the need to report them to his or her health care provider. Examples include having dark, tarry stools; shortness of breath; and frequent dyspepsia (indigestion).

For temporary relief of pain in a single joint, the health care provider may inject an individual joint with cortisone. Patients may have the same joint injected up to four times a year, or once every 3 months. Frequently injected joints

include the knee, base of the thumb, shoulder, and trochanteric bursa, which people often call the *hip*.

Other agents, such as hyaluronate (Hyalgan) and hylan GF 20 (Synvisc), are specific injections for knee and hip pain associated with OA. These synthetic joint fluid implants replace or supplement the body's natural hyaluronic acid, which is broken down by inflammation and aging.

Muscle relaxants, such as cyclobenzaprine hydrochloride (Flexeril), are sometimes given for painful muscle spasms, especially those occurring in the back from OA of the vertebral column. These drugs should be used with caution in older adults because they can cause acute confusion. *Remind the patient not to drive or operate dangerous machinery when taking muscle relaxants.*

Nonpharmacologic Interventions. In addition to analgesics, many nonpharmacologic measures can be used for patients with OA, such as rest balanced with exercise, joint positioning, heat or cold applications, weight control, and a variety of complementary and alternative therapies. Several types of rest are used to treat patients with OA:

- **Local rest** involves immobilizing any unstable joint, most often the knee, with a brace or splint. Knee braces improve balance, prevent falls, and decrease pain. If needed, the patient should use an ambulatory aid, such as a cane, to decrease stress on weight-bearing joints. *The cane should be used on the strongest side of the body.* Collaborate with the physical therapist (PT) to fit the patient for the appropriate device and explain its use.
- **Systemic rest** refers to immobilizing the entire body, such as during a nap. Teach the patient about the importance of sleeping about 8 to 10 hours and, if possible, resting an additional 1 to 2 hours each day.
- **Psychological rest** is equally important because it allows relief from the daily stresses that can enhance pain.

Teach the patient to *position joints in their functional position*. For example, when in a supine position (recumbent), he or she should use a small pillow under the head or neck but avoid the use of other pillows. The use of large pillows under the knees or head may result in flexion contractures. If needed, the legs may be elevated 8 to 12 inches (20 to 30 cm) to reduce back discomfort. Remind him or her to use proper posture when standing and sitting to reduce undue strain on the vertebral column. Teach the patient to wear supportive shoes; foot insoles may be helpful to relieve pressure on painful metatarsal joints. Collaborate with the PT to plan a program for muscle-strengthening exercises to better support the joints.

Most patients apply *heat* or *cold* for temporary relief of pain, but not all patients find these modalities effective. Heat may help decrease the muscle tension around the tender joint and thereby decrease pain. Suggest hot showers and baths, hot packs or compresses, and moist heating pads. *Regardless of treatment, teach him or her to check that the heat source is not too heavy or so hot that it causes burns.* A temperature just above body temperature is adequate to promote comfort.

If needed, collaborate with the PT to provide special heat treatments, such as paraffin dips, diathermy (using electrical current), and ultrasonography (using sound waves). A 15- to 20-minute application usually is sufficient to temporarily reduce pain, spasm, and stiffness. Cold packs or gels that feel hot and cold at the same time may also be used.

Cold therapy has limited use for most patients in controlling pain. Cold works by numbing nerve endings and decreasing secondary joint inflammation, if present.

! NURSING SAFETY PRIORITY

Action Alert

Teach the patient to use ice packs that are not too heavy. Do not place them directly on skin; instead, wrap them in a towel or soft cloth.

There is no one food that causes or cures arthritis. Instead, a well-balanced diet is recommended. Gradual *weight loss* for obese patients may lessen the stress on weight-bearing joints, decrease pain, and perhaps slow joint degeneration. If needed, collaborate with the registered dietitian to provide more in-depth teaching and meal planning or make referrals to community resources.

Complementary and Alternative Therapies. A variety of complementary and alternative medicine (CAM) therapies, especially *acupuncture*, have been effective for some patients (see [Chapter 2](#)). Topical *capsaicin* products may also be used. This expensive OTC drug may work by blocking substance P, a neurotransmitter for pain. Tell the patient to expect a burning sensation for a short time after applying capsaicin. Recommend the use of plastic gloves for application. To prevent burning of eyes or other body areas, wash hands immediately after applying the substance.

Dietary supplements may complement traditional drug therapies. Glucosamine and chondroitin are widely used and are the most effective nonprescription supplements taken to decrease pain and improve functional ability (Zhang et al., 2008). These natural products are found in and around bone cartilage for repair and maintenance. **Glucosamine** may decrease inflammation, and **chondroitin** may play a role in strengthening cartilage. These supplements may be used topically or taken in oral form. If no improvement is evident in 6 months of use, they should be discontinued (Zhang et al., 2008). [Chart 20-1](#) summarizes what you should teach your patients about glucosamine, with or without chondroitin.

CHART 20-1 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Considerations for Taking Glucosamine Supplements

- Tell your health care provider if you decide to take glucosamine.
- Do not take glucosamine if you have hypertension.
- Do not take glucosamine if you are pregnant or breast-feeding.
- Monitor for bleeding if you take chondroitin with glucosamine or chondroitin alone if you are on anticoagulant therapy.
- If diabetic, monitor your blood glucose levels carefully because taking glucosamine for a prolonged time can increase them.
- Be aware that glucosamine can cause adverse effects such as a rash; GI disturbances, especially diarrhea; drowsiness; and headache.
- Be sure to take the recommended dosage based on your weight.
- Read drug labels to ensure that you do not take too much glucosamine for your weight; some drug names may not indicate they contain glucosamine (e.g., Bioflex, Arth-X Plus, Nutri-Joint).

Surgical Management. Surgery may be indicated when conservative measures no longer provide pain control, when mobility becomes so restricted that the patient cannot participate in activities he or she enjoys, and when he or she cannot maintain the desired quality of life. The most common surgical procedure performed for *older adults* with OA is **total joint arthroplasty (TJA)** (surgical creation of a joint), also known as **total joint replacement (TJR)**. Almost any synovial joint of the body can be replaced with a prosthetic system that consists of at least two parts, one for each joint surface. TJAs are expected to increase exponentially as baby boomers age over the next 20 years.

A less invasive procedure using arthroscopy may be used to remove damaged cartilage (see [Chapter 52](#)). An **osteotomy** (bone resection) may be performed to correct joint deformity, but this procedure is done most commonly for younger adults (Zhang et al., 2008).

? DECISION-MAKING CHALLENGE

Patient-Centered Care; Evidence-Based Practice

A 60-year-old woman is admitted for an open reduction/internal fixation (ORIF) of her right ankle. After surgery, she will need to use crutches with no weight bearing on her affected leg for 4 to 6 weeks. When you are taking an admission history, she tells you that she has OA in her knees, feet, hands, and cervical spine. She takes ibuprofen when needed with some pain relief.

During her physical assessment, you note that the patient has multiple Heberden's and Bouchard's nodes on both hands. She has a joint effusion in her right third PIP, and she is right-handed.

1. What additional physical assessment do you need to perform to determine her level of functioning?
2. What other evidence-based interventions for OA pain might you recommend?
3. How might this patient's OA affect her ability to use crutches after surgery?
4. What health teaching is needed for this patient to help manage her OA and use crutches while her ankle heals?

Indications for Total Joint Arthroplasty. Total joint arthroplasty is a procedure used most often to manage the pain of OA and to improve mobility, although other conditions causing cartilage destruction may require the surgery. These disorders include RA, congenital anomalies, trauma, and osteonecrosis. **Osteonecrosis** is bony necrosis secondary to lack of blood flow, usually from trauma or chronic steroid therapy. Hip and knee joints are most commonly replaced, but finger and wrist joint, elbow, shoulder, toe joint, and ankle replacements have been improved in the past 15 years.

Contraindications to Total Joint Arthroplasty. The contraindications for TJA are active infection anywhere in the body, advanced osteoporosis, and rapidly progressive inflammation. An infection elsewhere in the body or from the joint being replaced can result in an infected TJA and subsequent prosthetic failure. Therefore if a patient has a urinary tract infection, for example, the physician treats the infection before surgery. Advanced osteoporosis can cause bone shattering during insertion of the prosthetic device. Severe medical problems, such as uncontrolled diabetes or hypertension, put the patient at risk for major postoperative complications and possible death.

As a group, TJAs are very successful. Many patients who have lived with chronic, unbearable pain for years and could not function independently at home or in the workplace now

longer experience pain in the diseased joint. The pain relief and psychological benefit often outweigh the perioperative risks and costs, but the surgeon and patient must make that decision. When the patient is older than 85 years, this decision may become an ethical issue in addition to a physical risk and cost-versus-benefit decision.

Total Hip Arthroplasty. The number of total hip arthroplasty (THA) procedures (also known as *total hip replacement [THR]*) has steadily increased over the past 30 years. The first time a patient receives any total joint arthroplasty, it is referred to as **primary arthroplasty**. If the implant loosens, **revision arthroplasty** may be performed. Availability of improved joint implant materials and better custom design features allow longer life of a replaced hip. Although patients of any age can undergo THR, the procedure is performed most often in those older than 60 years. The special needs and normal physiologic changes of older adults often complicate the perioperative period and may result in additional postoperative complications.

Preoperative Care. As with any procedure, preoperative care begins with assessing the patient's level of understanding about the surgery and his or her ability to participate in the postoperative plan of care. The surgeon explains the procedure and postoperative expectations (including possible complications) during the office visit, but this patient education may have occurred weeks or months before the scheduled surgery. Some patients may not know what questions to ask or may forget the important information that was taught. Information may be provided in a notebook or DVD format that the patient can take home to review and share with family. This is particularly useful to patients with poor reading skills or poor memory. Written materials or other media provided in the patient's language appropriate for the patient's educational level are essential.

An interdisciplinary plan of care that outlines expectations during preadmission, hospitalization, and posthospitalization phases of care should be reviewed with the patient and family or significant other. **Thomas and Sethares (2008)** investigated the effects of preoperative interdisciplinary patient education for patients having total hip or knee arthroplasty using a large quasi-experimental design. The researchers found that postoperative patients in the intervention group had a higher knowledge level than those patients who did not receive the structured preoperative education. A study by **Almada and Archer (2009)** described the positive outcomes for joint arthroplasty patients who were visited by an RN before and after surgery. Part of both visits included patient and family/caregiver education.

In some hospitals or orthopedic office practices, the physical therapist (PT) may have the patient practice transfers, positioning, and ambulation. An occupational therapist (OT) may partner with the PT to assist in exercises or learning to ambulate with an assistive device, such as crutches or a walker. In a systematic review of three available studies, **Barbay (2009)** found that preoperative exercises for patients having hip or knee arthroplasty had some benefits in improving postoperative outcomes, but the results were inconclusive.

The OT may also help obtain assistive/adaptive equipment that will be needed after surgery. The cost of some items, such as an elevated toilet seat, is covered by Medicare and other insurers because they are essential to prevent hip dislocation. Other helpful equipment may not be paid for by third-party

payers and can be purchased at local pharmacies or medical supply stores, based on the patient's specific needs. Examples include:

- Shower chair
- Handheld shower
- Long-handled sponge for bathing
- Reacher, grabber, or dressing stick
- Safety bars

All patients are also told to visit a dentist and have any necessary dental procedures done before surgery. After surgery, he or she must take extreme care not to acquire an infection that could migrate to the surgical area and cause prosthetic failure. *Remind the patient to tell any future health care provider that he or she has had a THA.*

In addition to usual preoperative laboratory tests, the surgeon may ask the patient with RA to have a cervical spine x-ray if he or she is having general anesthesia. Those with RA often have cervical spine disease that can lead to subluxation during intubation. Hip x-rays, computed tomography (CT) scan, and/or MRI may be done to assess the operative joint and surrounding soft tissues.

Because venous thromboembolism (VTE) is a serious postoperative complication, especially for hip surgery, the patient's risk factors for clotting problems are assessed, including history of previous clotting, obesity, smoking, and advanced age. *Drugs that increase the risks for clotting and bleeding, such as NSAIDs, vitamins C and E, and hormone replacement therapy (HRT), are discontinued about a week before surgery.*

Patients are also assessed for the need for possible blood transfusion after surgery. For patients who are at risk for postoperative anemia, one or more blood transfusions may be needed. Autologous (patient's own) or banked blood can be used. If desired, the patient may donate blood several weeks before surgery to be used after surgery. This pre-deposit autologous blood donation is a safe and cost-effective blood replacement alternative for those who are undergoing elective surgeries. It also decreases the risk for blood transfusion reactions.

For some patients, the surgeon may prescribe several weeks of epoetin alfa (Epogen, Procrit, Eprex ) with or without iron to prevent anemia that can occur after hip or knee replacement. Epoetin alfa is recombinant human erythropoietin, a substance that is essential for developing red blood cells. This drug is particularly useful for older adults, who frequently have mild anemia before surgery.

Remind patients that they will likely be asked to take a shower with special antiseptic soap the night before surgery to decrease bacteria that could cause infection after surgery. Tell them to wear clean nightwear after their shower and sleep on clean linen. Review which drugs are safe to take or necessary the morning of the operation, such as antihypertensives, and which ones should be avoided. Medication should be taken with a very small amount of water.

Operative Procedures. Similar to other orthopedic surgeries, the patient receives an IV antibiotic, usually a cephalosporin such as cefazolin (Ancef), at least 1 hour before the initial surgical incision is made or during the THA. Other drugs may be used for those who are allergic to cephalosporins.

The anesthesiologist or nurse anesthetist places the patient under general or **neuroaxial** (epidural/spinal) anesthesia for

lower extremity surgery. Neuroaxial induction reduces blood loss and the incidence of deep vein thrombosis. Intraoperative blood loss with hypotensive neuroaxial anesthesia is usually less than that with general anesthesia, thereby decreasing the need for postoperative blood transfusions.

Several types of incisions for hip replacement may be used. The more *traditional* 8-inch (20-cm) incision is usually longitudinal on the anterolateral thigh. The anterolateral approach results in more damage to muscle but less risk for dislocation. A posterior incision, posterolateral on the thigh and into the buttock, may be used to preserve muscle but may increase the risk for dislocation and sciatic nerve injury.

Some patients are candidates for *minimally invasive surgery* (MIS) using a smaller incision with special instruments to reduce muscle cutting. This newer technique cannot be used for patients who are obese or those with osteoporosis. It is done only for primary THAs, not for revision surgeries. Like those of any MIS, the benefits of minimally invasive THA are decreased soft tissue damage and postoperative pain. Patients often have a shorter hospital stay and quicker recovery. They are generally satisfied with the cosmetic appearance of the incision because there is less scarring. Postoperative complications are not as common in patients having minimally invasive (“mini”) hip replacements when compared with those having the traditional technique.

Regardless of procedure type, two components are used in the THA—the acetabular component and the femoral component (Fig. 20-2). A non-cemented prosthesis is most often used. Bone surfaces are smoothed as they are prepared to receive the artificial components. The non-cemented components are press-fitted into the prepared bone. The acetabular cup may be placed using computer assistance. If the prosthesis is cemented, polymethyl methacrylate (an acrylic fixating substance) is used. A closed wound drainage system may be placed in the wound before the surgeon closes the incision.

Considerations of a non-cemented prosthesis include protection of weight-bearing status to allow bone to grow into

the prosthesis and decreased problems with loosening of the prosthesis. With a cemented prosthesis, cement can fracture or deteriorate over time, leading to loosening of the prosthesis, which causes pain and can lead to the need for a revision arthroplasty. In revision arthroplasty, the old prosthesis is removed and new components are replaced. Bone graft may be placed if bone loss is significant. Outcomes from revision arthroplasty may not be as positive as with primary arthroplasty.

Postoperative Care. In addition to providing the routine postoperative care discussed in Chapter 18, assess for and help prevent possible postoperative complications. Table 20-2 summarizes these complications, including nursing measures for prevention, assessment, and intervention. Chart 20-2 highlights special concerns for the care of older adults in the postoperative period. Collaborate with your patient and his or her family to become safety partners to keep the patient free from harm, including complications, such as:

- Hip dislocation
- Venous thromboembolism (VTE)
- Infection
- Anemia
- Neurovascular compromise

Preventing Hip Dislocation. A major complication of THA is **subluxation** (partial dislocation) or total dislocation.

In some hospitals, abduction devices with straps are placed on patients who are restless or cannot follow instructions,

FIG. 20-2 A, Two major components of total hip arthroplasty. B, X-ray showing the components in place.

TABLE 20-2 NURSING INTERVENTIONS TO PREVENT COMPLICATIONS OF TOTAL JOINT ARTHROPLASTY

COMPLICATION	PREVENTION/INTERVENTION
Dislocation	Position correctly. For hip, keep leg slightly abducted. For hip, prevent hip flexion beyond 90 degrees. Assess for pain, rotation, and extremity shortening. Report immediately to physician.
Infection	Use aseptic technique for wound care and emptying of drains. Wash hands thoroughly when caring for patient. Culture drainage fluid, if change. Monitor temperature. Report excessive inflammation or drainage to physician.
Venous thromboembolism	Have patient wear elastic stockings and/or sequential compression device. Teach leg exercises to patient. Encourage fluid intake. Observe for signs of thrombosis (redness, swelling, or pain). Observe patient for changes in mental status. Administer anticoagulant as prescribed. Do not massage legs. Do not use knee gatch on bed.
Hypotension, bleeding, or infection	Take vital signs at least every 4 hours. Observe patient for bleeding. Report excessively low blood pressure or bleeding to physician.

especially older adults with delirium or dementia. One or two regular bed pillows are used in most cases to remind patients to keep their legs abducted. For devices with straps, be sure to loosen the straps every 2 hours and check the patient's skin for irritation or breakdown.

! NURSING SAFETY PRIORITY

Action Alert

Teach patients to maintain correct positioning at all times. When the patient returns from the postanesthesia care unit (PACU), place him or her in a supine position with the head slightly elevated. Place a pillow between the patient's legs to prevent adduction beyond the midline of the body.

CHART 20-2 NURSING FOCUS ON THE OLDER ADULT

Postoperative Care of the Older Adult with a Total Hip Arthroplasty

- Use an abduction pillow or splint to prevent adduction after surgery if the patient is very restless or has an altered mental state.
- Keep the patient's heels off the bed to prevent pressure ulcers.
- Do not rely on fever as a sign of infection; older patients often have infection without fever. Decreasing mental status typically occurs when the patient has an infection.
- When assisting the patient out of bed, move him or her slowly to prevent orthostatic (postural) hypotension.
- Encourage the patient to deep breathe and cough and to use the incentive spirometer every 2 hours to prevent atelectasis and pneumonia.
- As soon as permitted, get the patient out of bed to prevent complications of immobility.
- Anticipate the patient's need for pain medication, especially if he or she cannot verbalize the need for pain control.
- Expect a temporary change in mental state immediately after surgery as a result of the anesthetic and unfamiliar sensory stimuli. Reorient the patient frequently.

Place and support the affected leg in neutral rotation. *Keep the patient's heels off the bed to prevent skin breakdown, particularly older adults.* The procedure for postoperative turning is controversial and specified by agency policy or surgeon preference. In most cases, you are safe to turn the patient if the pillow is in place. Some surgeons allow only turning directly onto one side or the other, depending on the surgical approach.

Teach the patient and family about other precautions to prevent dislocation as outlined in [Chart 20-3](#). In addition to preventing adduction, remind them that the patient should avoid flexing the hips more than 90 degrees at all times. Use diagrams or demonstrate correct positioning to help reinforce this information before the patient gets out of bed ([Fig. 20-3](#)).

! NURSING SAFETY PRIORITY

Critical Rescue

Observe for possible signs of hip dislocation, which include increased hip pain, shortening of the affected leg, and leg rotation. If any of these clinical manifestations occur, keep the patient in bed and notify the surgeon immediately!

If the hip is dislocated, the surgeon manipulates and relocates the affected hip after the patient receives moderate sedation. The hip is then immobilized by an abduction splint or other device until healing occurs—usually in about 6 weeks.

Preventing Venous Thromboembolism. The most potentially life-threatening complication after THA is venous thromboembolism (VTE), which includes deep venous thrombosis (DVT) and pulmonary embolism (PE). Older patients are especially at increased risk for VTE because of age and decreased circulation before surgery. Obese patients and those with a history of VTE are also at high risk for thrombi. Sequential compression devices and/or antiembolism stockings are typically applied.

FIG. 20-3 Correct and incorrect hip flexion after a total hip replacement.

Anticoagulants, such as warfarin (Coumadin, Warfilone ) , subcutaneous low-molecular-weight heparin (LMWH), or factor Xa inhibitors, help prevent VTE. Patients are usually on anticoagulants for 3 to 6 weeks after surgery, depending on the patient's response and risk factors. During the past 20 years, the use of LMWHs has markedly increased for patients with total hip and knee replacements. Examples include enoxaparin (Lovenox), dalteparin (Fragmin), and tinzaparin (Innohep). These drugs work to inhibit factor Xa, which is a key component in the clotting process. Given in a low prophylactic dose based on the patient's weight, they do not significantly affect prothrombin time (PT) or activated partial thromboplastin time (aPTT).

Although not as commonly seen with these drugs when compared with unfractionated heparin (UFH), **thrombocytopenia** (decreased platelets) can occur. Therefore monitor the patient's complete blood count and platelet count per agency policy. Assess for bleeding, including occult blood in stool and bruising. Protamine sulfate can be given as an antidote for all heparins; however, it is not as effective for LMWH when compared with UFH. Be especially alert for signs and

symptoms of neurologic dysfunction because spinal and epidural hematomas can occur in patients who received neuroaxial anesthesia.

Fondaparinux (Arixtra), a factor Xa inhibiting agent, may also be prescribed for patients undergoing hip and knee arthroplasty. Its action is similar to that of LMWHs and has no effect on coagulation tests. Like other drugs, however, the patient is at risk for bleeding. No antidote exists at this time for fondaparinux. Like LMWHs, Arixtra is given for several days with an overlap while anticoagulants begin to work. A complete discussion of nursing care associated with patients taking anticoagulants and VTE is found in [Chapter 38](#). The Joint Commission's VTE Core Measures are also discussed in that chapter.

Early ambulation and exercise help prevent VTE. Teach the patient about leg exercises, which should begin in the immediate postoperative period and continue through the rehabilitation period. These exercises include plantar flexion and dorsiflexion (heel pumping), circumduction (circles) of the feet, gluteal and quadriceps muscle setting, and straight-leg raises (SLRs). Teach the patient to perform gluteal exercises by pushing the heels into the bed and achieve **quadriceps-setting exercises** ("quad sets") by straightening the legs and pushing the back of the knees into the bed. In addition to preventing clots, these exercises improve muscle tone, which helps restore the function of the extremity.

Preventing Infection. Another potential complication of hip replacement is infection. Infection can occur during hospitalization or months or years later. Most infections are caused by contamination during surgery.

Monitor the surgical incision and vital signs carefully—every 4 hours for the first 24 hours and every 8 to 12 hours thereafter. Observe for signs of infection, such as an elevated temperature and excessive or foul-smelling drainage from the incision. *An older patient may not have a fever with infection but, instead, may experience an altered mental state.* If you suspect infection, obtain a sample of any drainage for culture and sensitivity to determine the offending organisms and the antibiotics that may be needed for treatment.

Assessing for Bleeding and Managing Anemia. Observe the surgical hip dressing for bleeding or other type of drainage at least every 4 hours or when vital signs are taken. Empty and measure the bloody fluid in the surgical drain(s) every shift. The total amount of drainage is usually less than 50 mL/8 hr. Patients who have the minimally invasive procedure may not have a drain. The surgeon usually removes the drains and operative dressing 24 to 48 hours after surgery. *Take special care when removing tape from the skin to prevent tape burns as the surgical dressing is changed, especially for older adults.*

The surgeon also requests periodic hemoglobin and hematocrit (H&H) tests to assess for anemia. Although some patients receive several units of blood during surgery, the H&H levels may continue to fall; in this case, additional blood is given 1 to 2 days after surgery. Blood pressure may be lower than usual because of blood loss during surgery.

Assessing for Neurovascular Compromise. As with other musculoskeletal surgery, monitor neurovascular assessments frequently for a possible compromise in circulation to the affected distal extremity.

In addition to implementing interventions to prevent potential postoperative complications and monitoring for early signs of complications, the interdisciplinary team plans

CHART 20-3 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Care of Patients with Total Hip Arthroplasty After Hospital Discharge

Hip Precautions

- Do not sit or stand for prolonged periods.
- Do not cross your legs beyond the midline of your body.
- Do not bend your hips more than 90 degrees.
- Do not twist your body when standing.
- Use an ambulatory aid, such as a walker, when walking.
- Use assistive/adaptive devices for dressing, such as for putting on shoes and socks.
- Do not put more weight on your affected leg than allowed.
- Resume sexual intercourse as usual on the advice of your surgeon.

Pain Management

- Report increased hip pain to the physician immediately.
- Take oral analgesics as prescribed and only as needed.
- Do not overexert yourself; take frequent rests.

Incisional Care

- Inspect your hip incision every day for redness, heat, or drainage; if any of these are present, call your physician immediately.
- Cleanse your hip incision with a mild soap and water every day; be sure to dry it thoroughly.

Other Care

- Continue walking and performing the leg exercises as you learned in the hospital.
- Do not cross your legs to help prevent blood clots.
- Report pain, redness, or swelling in your legs to your physician immediately.
- Report chest pain or shortness of breath to your physician immediately.
- If you are taking an anticoagulant, follow the precautions learned in the hospital to prevent bleeding; avoid using a straight razor, avoid injuries, and report bleeding or excessive bruising to your surgeon immediately.
- Perform postoperative exercises as instructed, including straight leg raises, gluteal sets, ankle pumps, and "ham" sets.

! NURSING SAFETY PRIORITY

Action Alert

Check and document color, temperature, distal pulses, capillary refill, movement, and sensation. Remember to compare the operative leg with the nonoperative leg. These assessments are performed at the same time the vital signs are checked. Report any changes in neurovascular assessment to the surgeon, and carefully monitor for changes. Early detection of changes in neurovascular status can prevent permanent tissue damage.

care to manage pain, improve mobility and activity, and promote self-management.

? NCLEX EXAMINATION CHALLENGE

Physiological Integrity

An older woman had a left total hip arthroplasty yesterday afternoon. Which precautions will the nurse teach before helping the client transfer from the bed to the chair? **Select all that apply.**

- A. "Stand on your left leg and pivot to the chair."
- B. "Do not hyperflex your hips when sitting."
- C. "Cross your legs to be more comfortable."
- D. "Avoid twisting your body when moving."
- E. "Use your cane to help move into the chair."

Managing Pain. Although hip arthroplasty is performed to relieve joint pain, patients experience pain related to the surgical procedure. Many state that their pain is different and less severe than before surgery. Immediate pain control is typically achieved by extended-release epidural morphine (EREM) or patient-controlled analgesia (PCA) with morphine or another opioid. A study by Smith-Miller et al. (2009) found that there was no difference in pain control when these two methods were compared. [Chapter 5](#) contains information on the nursing care associated with these acute pain modalities. *Keep in mind that the patient may also receive other analgesics or anti-inflammatory drugs for chronic arthritic pain in other joints.*

Regardless of the pain management method used, most patients do not require parenteral analgesics after the first day. Oral opioids, such as oxycodone plus acetaminophen (Percocet, Tylox), are then commonly prescribed until the pain can be controlled by NSAIDs such as ketorolac (Toradol, Acular) or ibuprofen (Motrin, Apo-Ibuprofen .

Nonpharmacologic methods for acute and chronic pain control can also be used to decrease the amount of drug therapy used (see [Chapter 5](#)). A study by [Thomas and Sethares \(2010\)](#) found that guided imagery can be helpful in controlling pain in patients with total joint arthroplasty.

Promoting Mobility and Activity. Depending on the time of day that the surgery is performed, the patient with a THA usually

! NURSING SAFETY PRIORITY

Action Alert

Be sure to assist the patient the first time he or she gets out of bed to prevent falls and observe for dizziness. When getting the patient out of bed, stand on the same side of the bed as the affected leg. After the patient sits on the side of the bed, remind him or her to stand on the unaffected leg and pivot to the chair with guidance. *Do not lift the patient!*

gets out of bed the night of surgery to prevent complications (e.g., atelectasis, pneumonia), especially in older adults.

Remind the patient to avoid flexing the hips beyond 90 degrees as discussed earlier (see [Fig. 20-3](#)). Raised toilet seats and reclining chairs help prevent hyperflexion of the replaced hip joint. Be sure to teach the patient to also avoid twisting the body or crossing his or her legs to prevent hip dislocation.

The surgeon, type of prosthesis, and surgical procedure determine the amount of weight bearing that can be applied to the affected leg. A patient with a cemented implant is usually allowed immediate partial weight bearing (PWB) and progresses to full weight bearing (FWB). Typically, only "toe-touch" or minimal weight bearing is permitted for patients with uncemented prostheses. When x-ray evidence of bony ingrowth can be seen, the patient can progress to PWB and then to FWB.

In collaboration with the physical therapist (PT), teach the patient how to follow weight-bearing restrictions. Most patients use a walker (may be a rolling walker), but younger adults may use crutches. They are usually advanced to a single cane or crutch if they can walk without a severe limp 4 to 6 weeks after surgery. When the limp disappears, they no longer need an ambulatory/assistive device and may be permitted to sit in chairs of normal height, use regular toilets, and drive a car.

Promoting Self-Management. The hospital's occupational therapy department often supplies assistive/adaptive devices to help with ADLs, especially for those having traditional surgery. Particularly important are devices designed for reaching to prevent patients from bending or stooping and flexing the hips more than 90 degrees. Extended handles on shoehorns and dressing sticks may be very useful to achieve ADL independence. Third-party payers may or may not pay for these devices, depending on the patient's status.

For those who have *traditional surgery*, the length of stay in the acute care hospital is typically 3 days, but older adults or those experiencing postoperative complications may stay longer. Those who have the *minimally invasive THA* are discharged on the second postoperative day or the day of surgery (23-hour stay). Those patients are discharged to home on crutches to practice their own rehabilitative exercises. Most of them are able to return to work in 2 weeks. For that reason, some hospitals have started Rapid Recovery Hip Replacement programs for patients who are candidates for MIS.

Discharge for patients having *traditional surgery* may be to the home, a rehabilitation unit, a transitional care unit, or a skilled unit or long-term care facility for continued rehabilitation before discharge to home. The interdisciplinary team provides written instructions for posthospital care and reviews them with patients and their family members (see [Chart 20-3](#)). Be sure to provide a copy of these instructions for the patient.

Acute rehabilitation usually takes 1 to 2 weeks or longer, depending on the patient's age and tolerance and the type of prosthesis used. However, it often takes 6 weeks or longer for complete recovery. Some patients who are discharged to their home are able to attend physical therapy sessions in an office or ambulatory care setting. Others have no means or cannot use community resources and need physical therapy in the home, depending on their health insurance coverage.

Collaborate with the case manager to determine which option is best for your patient.

Total Knee Arthroplasty. Although many adults require total knee arthroplasty (TKA, also known as *total knee replacement* [TKR]), those who have a knee replaced are often younger than those who have a hip replaced. Continued improvements in total knee implants in the past 15 years have increased the expected life of a TKA to 20 years or more, depending on the age and activity level of the patient. An increasing number of patients who have TKAs are overweight or obese. Obesity increases wear and tear on weight-bearing joints, which can lead to revision surgeries. Unilateral (one joint) or bilateral joint replacements done at the same time may be performed, depending on the patient.

Preoperative Care. TKA, like hip replacement, is performed when joint pain cannot be managed by conservative measures. When activity and mobility severely prevent patients from participating in work or activities they enjoy, this procedure can restore a high quality of life. The preoperative care and teaching for patients undergoing a TKA are similar to that for total hip replacement. However, precautions for positioning are not the same. Differences in patient and family teaching depend on the procedure used by the orthopedic surgeon.

Like the minimally invasive surgery (MIS) for the hip, the knee can also be replaced using MIS. Candidates for mini-knee replacement cannot have severe bone loss, obesity, or previous knee surgery. They should be in good general health. Patients having MIS usually have less blood loss during surgery, less pain, more joint range of motion (less stiffness from scarring), and a faster recovery, leading to a shorter hospital stay. Rapid Recovery Knee Replacement programs for patients having minimally invasive TKA are becoming popular in a number of hospitals.

All patients are given verbal and either written or video preoperative instructions, which include the activity protocol to follow after surgery. The PT and OT provide information about transfers, ambulation, postoperative exercises, and ADL assistance. Patients may practice walking with walkers or crutches to prepare them for ambulation after TKA. Teach patients about the possible need for assistive-adaptive devices to assist with ADLs, including an elevated toilet seat, safety handrails, and dressing devices like a long-handled shoe-horn. Some third-party payers cover these devices, depending on the patient's condition and age; however, other insurers may not pay for them. Teach the patient and family where this equipment can be purchased to have it available after surgery.

Some surgeons prescribe a continuous passive motion (CPM) machine after knee surgery to increase joint mobility. Others have found that the range of motion for the surgical knee is not improved by using this device. If the patient will have a CPM machine after surgery, be sure to explain what it is and how it is used.

Routine diagnostic testing is requested, as well as any additional tests, such as cervical spine x-rays for patients with rheumatoid arthritis (RA) to determine if the patient can be intubated for anesthesia. Knee x-rays, CT scan, and/or MRI may be done to assess the joint and surrounding soft tissues.

Teach patients that they will need to shower with a special antiseptic soap the night before surgery to decrease bacteria on the skin that could cause infection after surgery. Remind

them to wear clean nightwear and sleep on clean linen. Ask them to check with their surgeon about what medications they can take the morning of surgery, including antihypertensives. Take these drugs with a small amount of water to prevent vomiting and aspiration during surgery.

Operative Procedures. As with the hip, the knee can be replaced with the patient under general or neuroaxial (epidural or spinal) anesthesia. An antibiotic, usually an IV ceph-alosporin, is given shortly before surgical opening. In the *traditional surgery*, the surgeon makes a central longitudinal incision about 8 inches (20 cm) long. Osteotomies of the femoral and tibial condyles and of the posterior patella are performed, and the surfaces are prepared for the prosthesis. The femoral component is often non-cemented (using a press-fit) with the tibial component being cemented. The surgeon typically inserts a surgical drain and applies a pressure dressing to decrease edema and bleeding.

Minimally invasive TKA may be performed using a shorter incision and special instruments to spare muscle and other soft tissue. Computer-guided equipment may be used to ensure accurate positioning of the knee implants. This procedure is referred to as a *computer-assisted TKA*.

Complementary and Alternative Therapies. An experimental treatment to reduce the severe pain that occurs after knee arthroplasty is the intraoperative insertion of Adlea, a refined capsaicin product, directly into the surgical joint. Capsaicin binds to and opens C fiber receptors, especially TRPV1, which causes extra calcium to enter the nerve cells. The cells become overloaded and shut down, causing numbness. Preliminary results from several studies show that patients who were given Adlea during knee surgery had less acute postoperative pain when compared with others who did not receive the treatment. Additional studies for patients having total hip replacements and bunionectomies are currently being conducted. Adlea could help decrease the need for opioid analgesia for many patients having surgery (Remadevi & Szallisi, 2008).

Postoperative Care. Postoperative nursing care of the patient with a TKA is similar to that for the patient with a total hip arthroplasty; however, maintaining hip abduction is not necessary. The surgeon may prescribe a CPM machine, which can be applied in the postanesthesia care unit (PACU) or soon after the patient is admitted to the postoperative unit (Fig. 20-4). The CPM machine keeps the prosthetic knee in motion and may prevent the formation of scar tissue, which could decrease knee mobility and increase postoperative pain. In the immediate postoperative period, the surgeon may also prescribe ice packs or other cold therapy to decrease swelling at the surgical site. Swelling and bruising are more common with this type of surgery than with hip surgery.

The surgeon, PT, or technician presets the CPM machine for the appropriate range of motion and cycles per minute. A typical initial setting is 20 to 30 degrees of flexion and full extension (0 degrees) at two cycles per minute, but this setting varies according to surgeon preference. The machine is generally used on an intermittent schedule of a designated number of hours several times a day, with the range of motion increased gradually. Observe and document the patient's response to the device, and follow the surgeon's protocol for settings. [Chart 20-4](#) outlines your responsibility when caring for a patient using the CPM machine.

FIG. 20-4 A continuous passive motion (CPM) machine in use.

CHART 20-4 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

The Patient Using a Continuous Passive Motion (CPM) Machine

- Ensure that the machine is well padded.
- Check the cycle and range-of-motion settings at least once every 8 hours.
- Ensure that the joint being moved is properly positioned on the machine.
- If the patient is confused, place the controls to the machine out of his or her reach.
- Assess the patient's response to the machine.
- Turn off the machine while the patient is having a meal in bed.
- When the machine is not in use, do not store it on the floor.

In general, pain-control measures for patients with TKA are similar to those with total hip arthroplasty. Many patients report high ratings on the pain intensity scale and require IV opioid medications longer than patients with THA, particularly if they have had bilateral surgery. *Be sure to manage your patient's pain to provide comfort, increase his or her participation in physical therapy, and improve joint mobility.*

One of the most recent advances in postoperative pain management for lower extremity total joint arthroplasty is *peripheral nerve blockade (PNB)*. In this procedure, the anesthesiologist injects the femoral or sciatic nerve with local anesthetic; the patient may receive a continuous infusion of the anesthetic by portable pump. This method of pain management not only decreases pain but also allows patients to participate in rehabilitation earlier than when using opioid analgesia alone. Patients having continuous femoral nerve blockade (CFNB) after TKA require less opioids and antiemetics when compared with patients receiving no CFNB and those who had a single-shot FNB. A study by [Leach and Bonfe \(2009\)](#) also found that patients with nerve blocks had better flexion and extension of the knee when compared with those who had either general or epidural/spinal anesthesia.

When caring for a patient receiving a CPNB, perform neurovascular assessments every 2 to 4 hours or according to hospital protocol. The patient should be able to plantar flex and dorsiflex the affected foot but not feel pain in the

! NURSING SAFETY PRIORITY

Critical Rescue

Monitor the patient for signs and symptoms that could indicate that the local anesthetic is getting into the patient's system, such as:

- Metallic taste
- Tinnitus
- Nervousness
- Slurred speech
- Bradycardia
- Hypotension
- Decreased respirations
- Seizures

Report any of these new signs and symptoms to the surgeon or anesthesiologist immediately, and carefully continue monitoring the patient for changes.

extremity. Check for movement, sensation, warmth, color, pulses, and capillary refill.

Because dislocation is a rare problem for a patient with TKA, special positioning to prevent adduction is not required. Maintain the knee in a neutral position and not rotated internally or externally. If a CPM machine is not used, the surgeon may recommend that the knee should rest flat on the bed or with one pillow under the lower calf and foot to encourage slight extension of the knee joint. Be sure that the surgical knee does not hyperextend.

Some complications that affect patients with total hip arthroplasty may also affect those having TKA, such as venous thromboembolism, infection, anemia, and neurovascular compromise. Assessments and interventions associated with these complications are described in the Postoperative Care section of the discussion of Total Hip Arthroplasty on pp. 325-328.

The desired outcome for discharge from the acute hospital unit is that the patient can walk independently with crutches, walker, or cane and has adequate flexion in the operative knee for ambulation. Patients who had minimally invasive TKA are discharged to home in 2 days with instructions for postoperative exercises, weight bearing, and activity progression. Many of these instructions (except for preventing hip dislocation) are similar to those provided for teaching patients after a total hip arthroplasty (see [Chart 20-3](#)).

Patients are able to partially weight bear unless the prosthesis is not cemented. During the home rehabilitation phase, the use of a stationary bicycle or CPM machine may help gain flexion. These patients can return to work and other usual activities in 2 to 3 weeks, depending on their age and other health status factors.

Acute rehabilitation for *traditional* TKA usually takes about 1 to 2 weeks longer, depending on the age and tolerance of the patient. These patients may be discharged to their home or to an acute rehabilitation unit, transitional care unit, skilled unit, or long-term care facility for therapy. If able, they may attend physical therapy sessions in an office or ambulatory care setting. If not, home care services can provide physical therapy in their home, depending on the insurance available. *Collaborate with the case manager to determine which option is best for your patient.* Total recovery from traditional TKA takes 6 weeks or longer, especially for those older than 75 years.

Other Joint Arthroplasties. After the hip and knee, the shoulder and hand are the most common joints replaced for

NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

A nursing assistant (NA) is assigned to care for a client who has a CPM machine in place after a total knee arthroplasty. Which statement by the NA indicates a need for further teaching and supervision by the nurse?

- A. "I will turn off the machine if the client has any pain."
- B. "I will turn off the machine when the client eats."
- C. "I will store the machine on a chair when not used."
- D. "I will check to make sure the client's leg is correctly placed."

severe OA, RA, or trauma. Elbow, wrist, ankle, and foot replacements are not performed as often as other types of arthroplasties. The shoulder and other upper extremity joints do not bear weight and therefore tend to have less degeneration and subsequent pain. Preoperative teaching for patients having any of these surgeries depends on the surgeon's technique and postoperative protocols. For example, the continuous passive motion (CPM) machine may be prescribed postoperatively in the hospital and in the posthospital setting (home or other facility). These devices are available for almost any joint surgery in the body. Some surgeons find that the CPM machine is not helpful in promoting joint mobility and may be uncomfortable for patients.

Total shoulder arthroplasty (TSA) has gained popularity as newer prostheses and technology have been developed. This procedure usually decreases arthritic pain and increases the patient's ability to perform ADLs. Because the shoulder joint is complex and has many **articulations** (joint surfaces), **subluxation** (partial dislocation) or complete dislocation is a major potential complication. Usually the glenohumeral joint, created by the glenoid cavity of the shoulder blade (scapula) and the head of the humerus, is replaced because it moves the most and is therefore most affected by arthritis. A **hemiarthroplasty** (replacement of part of the joint), typically the humeral component, may be performed as an alternative to TSA.

The surgeon makes an incision to replace the joint while the patient is under general anesthesia. The implant may be cemented or press-fitted without cement. Some surgeons perform *minimally invasive TSA*, which decreases postoperative complications like infection and nerve damage. A sling is applied to immobilize the joint until therapy begins.

In addition to dislocation, postoperative complications are similar to those for other total joint replacements and include infection and neurovascular compromise. Active and passive exercises are needed to begin shoulder movement. *As for any other total joint arthroplasty, perform frequent neurovascular assessments, at least every 4 to 8 hours.* The hospital stay for TSA is shorter than for a total hip or knee replacement—usually 1 to 2 days until pain is controlled. Rehabilitation with an occupational therapist generally takes several months.

Total elbow arthroplasty (TEA) is performed most often for patients with rheumatoid arthritis (RA), but it is done for anyone whose severe arthritis limits movement and causes uncontrolled pain. TEA may be successful in increasing range of motion, but infection and loosening may occur because of extensive tissue cutting during surgery. Active and passive exercises are used postoperatively. In general, elbow motion is allowed as tolerated. Occupational therapy may not be necessary, but the need depends on the individual patient.

Lifting is usually restricted on a long-term basis after TEA. Generalized swelling usually resolves in 3 to 6 months.

Any joint of the hand or foot can be replaced (*phalangeal joint, metacarpal or metatarsal arthroplasties*), often for patients with RA. Hand prostheses are implanted without the use of cement because they stay in place and do not bear weight.

For the hand, a bulky dressing is used temporarily after surgery and is then replaced with a dynamic splint. Edema is controlled by having the patient elevate the arm as much as possible. The rehabilitation program for phalangeal joint arthroplasties may last for many weeks until normal function and strength return. These procedures are typically performed in specialized hand centers. Joint replacements in the toe usually require less rehabilitation.

Any bone of the *wrist* can also be replaced, including the heads of the radius and ulna. The postoperative pressure dressing is removed in 1 to 2 days, and a splint is applied. The patient usually regains full function within 6 to 12 weeks, but lifting may be restricted for a longer period. Special hand therapists work with these patients for the extensive rehabilitation that is required for phalangeal and wrist replacements.

Because the ankles support about 25% of the body's weight and are complex joints, developing an implant that is both small enough and strong enough has been difficult. Although total ankle arthroplasties (TAAs) have been problematic for more than three decades, newer non-cemented prosthetic systems have renewed interest in ankle replacements. Surgeons who specialize in foot and ankle surgeries are available in some parts of the country.

Postoperative complications include infection, delayed wound healing, nerve injuries, and loosening. Therefore TAA is not as successful as total hip or knee replacements. Non-cemented prostheses seem to be preferred over cemented ones to prevent loosening. The patient is allowed to begin weight bearing at about 6 weeks, and rehabilitation continues for about 3 months.

Improving Mobility

Planning: Expected Outcomes. The patient with osteoarthritis (OA) is expected to maintain or improve a level of mobility and activity that allows him or her to function independently with or without an assistive ambulatory device.

Interventions. Management of the patient with OA is an interdisciplinary effort. If needed, collaborate with the physical therapist (PT) and occupational therapist (OT) to meet the outcome of independent function and mobility. Major interventions include therapeutic exercise and the promotion of ADLs and ambulation by teaching about health and the use of assistive devices.

Two types of *exercise* are recommended for the patient with OA: recreational and therapeutic. **Recreational exercise** includes hobbies and sports, with no planned purpose other than relaxation. **Therapeutic exercise** includes carefully planned activities that are designed to improve muscle strength, muscle tone, and joint range of motion. Therapeutic exercise can also reduce pain and improve the patient's psychological health.

Certain recreational activities may also be therapeutic, such as swimming to enhance chest and arm muscles. Aerobic exercises (e.g., walking, biking, swimming, aerobic dance) are

CHART 20-5 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Exercises for Patients with Osteoarthritis or Rheumatoid Arthritis

- Follow the exercise instructions that have been prescribed specifically for you. There are no universal exercises; your exercises have been specifically tailored to your needs.
- Do your exercises on both “good” and “bad” days. Consistency is important.
- Respect pain. If pain increases as you exercise, stop and report this to your health care provider.
- Use active rather than active-assist or passive exercise whenever possible.
- Reduce the number of repetitions when the inflammation is severe and you have more pain.
- Do not substitute your normal activities or household tasks for the prescribed exercises.
- Avoid resistive exercises when your joints are severely inflamed.

recommended. Exercises may be prescribed by rehabilitation therapists for the patient with OA, but you will need to reinforce their techniques and principles. The ideal time for exercise is immediately after the application of heat. To prevent further joint damage, teach patients to carefully follow the instructions for exercise outlined in [Chart 20-5](#).

Collaborate with the PT to evaluate the patient’s need for ambulatory aids such as canes, walkers, or platform crutches. Although some patients do not like to use these aids or may forget how to use them, they can help prevent further joint deterioration and pain. Collaborate with the OT, if needed, to provide suggestions and devices for assistance for ADLs.

Community-Based Care

The patient with OA is not usually hospitalized for the disease itself but for surgical management. Expect that any patient older than 60 years will have some degree of arthritis and possibly chronic pain that needs to be managed.

Home Care Management

If weight-bearing joints are severely involved, the patient may have difficulty going up or down stairs. Making arrangements to live on one floor with accessibility to all rooms is often the best solution. A home care nurse or case manager may collaborate with a rehabilitation therapist to assess the need for structural alterations to the home to accommodate ambulatory aids and enable the patient to perform ADLs. For example, a kitchen counter may need to be lowered or a seat and handrails may need to be installed in the shower. If the patient has undergone a total hip replacement, an elevated toilet seat is necessary for several weeks postoperatively to prevent excessive hip flexion. Patients who have TKAs may also find elevated toilet seats easier to use.

Teaching for Self-Management

Learning how to protect joints is the most important part of patient and family education. Preventing further damage to joints slows the progression of OA and minimizes pain. Explain the general principles of joint protection, and give practical examples ([Chart 20-6](#)).

CHART 20-6 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Evidence-Based Instructions for Joint Protection

- Use large joints instead of small ones; for example, place your purse strap over your shoulder instead of grasping the purse with your hand.
- Do not turn a doorknob clockwise. Turn it counterclockwise to avoid twisting your arm and promoting ulnar deviation.
- Use two hands instead of one to hold objects.
- Sit in a chair that has a high, straight back.
- When getting out of bed, do not push off with your fingers; use the entire palm of both hands.
- Do not bend at your waist; instead, bend your knees while keeping your back straight.
- Use long-handled devices, such as a hairbrush with an extended handle.
- Use assistive/adaptive devices, such as Velcro closures and built-up utensil handles, to protect your joints.
- Do not use pillows in bed except a small one under your head.
- Avoid twisting or wringing your hands.

As with other diseases in which drugs and nutritional therapy are used, teach the patient and family the drug therapy protocol, desired effects and potential side effects, and toxic effects. Emphasize the importance of reducing weight and eating a well-balanced diet to promote tissue healing.

Many patients with arthritis look for a cure after becoming frustrated and desperate about the course of the disease and treatment. Better control of arthritis is possible, but cure is not yet available. Unfortunately, tabloids, books, media, and the Internet often report “curative” remedies. People spend billions of dollars each year on quackery, including liniments, special diets, and copper bracelets. More hazardous substances, such as snake venom and industrial cleaners, are also advertised as remedies. Refer the patient to the Arthritis Foundation for up-to-date information about these “cures.” The practice of wearing a copper bracelet will not cure arthritis, but it will not cause harm. If the patient is using a potentially harmful substance or method, however, reinforce the need to avoid the unproven remedy and explain why it should not be used. Respect the patient’s preferences, values, and beliefs for using benign remedies that do not cause harm.

With most types of arthritis and connective tissue disease (CTD), patients must live with a chronic, unpredictable, and painful disorder. Their roles, self-esteem, and body image may be affected by these diseases. Body image is often not as devastating in OA as in the inflammatory arthritic diseases, such as RA. The psychosocial component is discussed in more detail in the Psychosocial Assessment section on p. 335 of the Rheumatoid Arthritis section.

Health Care Resources

The patient who has undergone surgery may need help from community resources. After an arthroplasty, he or she needs extensive assistance with mobility. The patient may be discharged to home or an inpatient unit. Collaborate with the case manager and surgeon to determine the best placement. If the patient is discharged to home, home care nurses may

be approved for third-party payment for several visits, depending on the presence of any existing systemic diseases. A home care aide may visit the home to help with hygiene-related needs, and a physical therapist may work with ambulatory and mobility skills. For older patients, a family member, significant other, or other caregiver should be in the home for at least the first few weeks when the patient needs the most assistance. Emphasize the need for patient safety, especially interventions to prevent falls as described in Chapter 3.

Provide written instructions about the required care, regardless of whether the patient goes home or to another inpatient facility. As required by The Joint Commission's National Patient Safety Goals (NPSGs), hand-off communication with the new care provider is essential for seamless continuity of care.

The Arthritis Foundation (www.arthritis.org) is an important community resource for all patients with arthritis and CTD. This organization provides information to lay people and health care professionals and refers patients and their families to other resources as needed. Local support groups can help them cope with these diseases.

EVALUATION: OUTCOMES

Evaluate the care of the patient with OA on the basis of the identified priority problems. The expected outcomes are that he or she:

- Achieves pain control to a pain intensity level of 3 to 4 on a scale of 0 to 10 or at a level that is acceptable to for the patient
- Moves and functions in his or her own environment independently with or without assistive devices

RHEUMATOID ARTHRITIS

Pathophysiology

Rheumatoid arthritis (RA) is a common connective tissue disease that can be the most destructive to the joints. It is a chronic, progressive, systemic inflammatory autoimmune disease process that affects primarily the synovial joints. **Systemic** means this disease affects the body system, affecting many joints and other tissues. RA affects over 1.3 million people, and European Americans have the disease more often than other groups (Arthritis Foundation, 2011b). The cause for this trend is not known.

In RA, transformed autoantibodies (rheumatoid factors [RFs]) are formed that attack healthy tissue, especially synovium, causing inflammation. The disease then begins to involve the articular cartilage, joint capsule, and surrounding ligaments and tendons. Several processes cause cartilage damage in patients with RA (McCance et al., 2010):

- CD4 T-helper cells and other immune cells in synovial fluid promote cytokine release, especially interleukin-1 (IL-1) and tumor necrosis factor—alpha (TNF α), which attack cartilage.
- Neutrophils and other inflammatory cells in the joint are activated and break down the cartilage.
- Immune complexes deposit in synovium, and osteoclasts are activated.
- B- and T-lymphocytes of the immune system are stimulated and increase the inflammatory response. (Also

see Chapter 19 for a complete discussion of the inflammatory response.)

The synovium then thickens and becomes hyperemic, fluid accumulates in the joint space, and a pannus forms. The **pannus** is vascular granulation tissue composed of inflammatory cells; it erodes articular cartilage and eventually destroys bone. As a result, in late disease, fibrous adhesions, bony ankylosis, and calcifications occur; bone loses density, and secondary osteoporosis occurs.

Permanent joint changes may be avoided if RA is diagnosed early. Early, aggressive treatment to suppress synovitis may lead to a remission. RA is a disease characterized by natural remissions and exacerbations. Interdisciplinary management helps control the disease to decrease the intensity and number of exacerbations. Preventing flares helps prevent joint erosion and permanent joint damage.

Because rheumatoid arthritis is a systemic disease, areas of the body besides the synovial joints can be affected. Inflammatory responses similar to those occurring in synovial tissue may occur in any organ or body system in which connective tissue is prevalent. If blood vessel involvement (**vasculitis**) occurs, the organ supplied by that vessel can be affected. The result is malfunction and eventual failure of the organ or system. These pathologic changes may occur late in the disease process and cause life-threatening problems.

The etiology of RA remains unclear, but research suggests a *combination of environmental and genetic factors*. Some researchers also suspect that female reproductive hormones influence the development of RA because it affects women more often than men—usually young to middle-aged women. Others suspect that infectious organisms may play a role, particularly the Epstein-Barr virus (McCance et al., 2010). Physical and emotional stresses have been linked to exacerbations of the disorder and may be contributing factors or “triggers” to its development.

GENETIC/GENOMIC CONSIDERATIONS

Research has shown that there is a strong association between RA and several human leukocyte antigen (HLA)-DR alleles. The cause of this association is not clear, but most HLA diseases are autoimmune (Nussbaum et al., 2007). DR alleles, especially *DR4* and *DRB1*, are the primary genetic factors contributing to the development of RA. *DR4* is associated with more severe forms of the disease (Klippel, 2007). Other contributing factors are being researched.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

The onset of rheumatoid arthritis (RA) may be acute and severe or slow and progressive; patients may have vague symptoms that last for several months before diagnosis. The onset of the disease is more common in the winter months than in the warmer months. The manifestations of RA can be categorized as early or late disease and as articular (joint) or extra-articular (Chart 20-7).

Physical Assessment/Clinical Manifestations

Early Disease Manifestations. The patient with RA typically reports joint stiffness, swelling, pain, and fatigue. He or she may report generalized weakness and morning stiffness.

CHART 20-7 KEY FEATURES

The Patient with Rheumatoid Arthritis**Early Manifestations****Joint**

- Inflammation

Systemic

- Low-grade fever
- Fatigue
- Weakness
- Anorexia
- Paresthesias

Late Manifestations**Joint**

- Deformities (e.g., swan neck or ulnar deviation)
- Moderate to severe pain and morning stiffness

Systemic

- Osteoporosis
- Severe fatigue
- Anemia
- Weight loss
- Subcutaneous nodules
- Peripheral neuropathy
- Vasculitis
- Pericarditis
- Fibrotic lung disease
- Sjögren's syndrome
- Renal disease
- Felty's syndrome

Anorexia and a weight loss of about 2 or 3 pounds (1 kg) usually occur early in the disease process. Persistent low-grade fever may accompany these manifestations. In patients with early disease, the upper-extremity joints are involved initially—often the proximal interphalangeal (PIP) and metacarpophalangeal (MCP) joints of the hands. These joints may be slightly reddened, warm, stiff, swollen, and tender or painful, particularly on palpation (caused by synovitis). The typical pattern of joint involvement in RA is bilateral and symmetric (e.g., both wrists), and the number of joints involved usually increases as the disease progresses. In early disease, the patient may report migrating symptoms known as **migratory arthritis**.

The presence of only *one* hot, swollen, painful joint (out of proportion to the other joints) may mean the joint is infected. *Refer the patient to the health care provider (generally the rheumatologist) immediately if this is the case.* Single hot, swollen joints are considered infected until proven otherwise and require immediate long-term antibiotic treatment.

Late Disease Manifestations. As the disease worsens, the joints become progressively inflamed and very painful. The patient usually has frequent morning stiffness (also called the **gel phenomenon**), which lasts for 45 minutes to several hours after awakening. On palpation, the joints feel soft and look puffy because of synovitis and **effusions** (joint swelling with fluid, especially the knees). The fingers often appear spindle-like. Note any muscle atrophy (which can result from disuse secondary to joint pain) and a decreased range of motion in the affected joints.

FIG. 20-5 Common joint deformities seen in rheumatoid arthritis.

Most or all synovial joints are eventually affected. The temporomandibular joint (TMJ) may be involved in severe disease, but such involvement is uncommon. When the TMJ is affected, the patient may have pain when chewing or opening the mouth.

When the spinal column is involved, the cervical joints are most likely to be affected. During clinical examination, gently palpate the posterior cervical spine and identify it as cervical pain, tenderness, or loss of motion.

! NURSING SAFETY PRIORITY

Critical Rescue

Cervical disease may result in subluxation, especially the first and second vertebrae. This complication may be life threatening because branches of the phrenic nerve that supply the diaphragm are restricted and respiratory function may be compromised. The patient is also in danger of becoming quadriparetic (weak in all extremities) or quadriplegic (paralyzed in all extremities). If a person with RA reports cervical pain (may radiate down one arm) or loss of range of motion in the cervical spine, notify the health care provider immediately.

Joint Involvement. *Joint deformity* occurs as a late, articular manifestation, and secondary osteoporosis can cause bone fractures. Observe common deformities, especially in the hands and feet (Fig. 20-5). Extensive wrist involvement can result in carpal tunnel syndrome (see [Chapter 54](#) for assessment and management of carpal tunnel syndrome).

Gently palpate the tissues around the joints to elicit pain or tenderness associated with other rheumatoid complications, unless the patient is having severe joint pain. For example, **Baker's cysts** (enlarged popliteal bursae behind the knee) may occur and cause tissue compression and pain. Tendon rupture is also possible, particularly rupture of the Achilles tendon.

Systemic Complications. Numerous extra-articular clinical manifestations are associated with advanced disease. Assess other body systems to ascertain systemic involvement. In addition to increased joint swelling and tenderness, moderate to severe *weight loss, fever, and extreme fatigue* are common in late disease **exacerbations**, often called “flare-ups.” Some patients have the characteristic round, movable, nontender **subcutaneous nodules**, which usually appear on the ulnar surface of the arm, on the fingers, or along the Achilles tendon. These nodules can disappear and reappear

at any time and are associated with severe, destructive disease. Rheumatoid nodules usually are not a problem themselves; however, they occasionally open and become infected and may interfere with ADLs. Accidentally bumping the nodules may cause discomfort or pain. Occasionally, nodules occur in the lungs.

Inflammation of the blood vessels results in *vasculitis*, particularly of small to medium-size vessels. When arterial involvement occurs, major organs and body systems become ischemic and malfunction. Assess for ischemic skin lesions that appear in groups as small, brownish spots, most commonly around the nail bed (**periungual lesions**). Monitor the number of lesions, note their location each day, and report vascular changes to the health care provider. Increased lesions indicate increased vasculitis, and a decreased number indicates decreased vasculitis. Also carefully assess any larger lesions that appear on the lower extremities. These lesions can lead to ulcerations, which heal slowly as a result of decreased circulation. Peripheral neuropathy associated with decreased circulation can cause footdrop and **paresthesias** (burning and tingling sensations), usually in older adults.

Respiratory complications may manifest as *pleuritis*, *pneumonitis*, *diffuse interstitial fibrosis*, and *pulmonary hypertension*. Cardiac complications include *pericarditis* and *myocarditis*. These health problems are discussed elsewhere in this text. Assess for eye involvement, which typically manifests as *iritis* and *scleritis*. If either of these complications is present, the sclera of one or both eyes is reddened and the pupils have an irregular shape.

Associated Syndromes. Several syndromes are seen in patients with advanced RA. The most common is **Sjögren's syndrome**, which includes a triad of:

- Dry eyes (keratoconjunctivitis sicca [KCS], or the sicca syndrome)
- Dry mouth (**xerostomia**)
- Dry vagina (in some cases)

Note the patient's report of dry mouth or dry eyes. Some patients state that their eyes feel "gritty," as if sand is in their eyes. Inspect the mouth for dry, sticky membranes and the eyes for redness and lack of tearing.

Less commonly observed is **Felty's syndrome**, which is characterized by RA, hepatosplenomegaly (enlarged liver and spleen), and leukopenia. **Caplan's syndrome** is characterized by the presence of rheumatoid nodules in the lungs and pneumoconiosis, which is noted primarily in coal miners and asbestos removal workers.

Psychosocial Assessment

Rheumatoid arthritis (RA) and other inflammatory types of arthritis are chronic diseases that can be crippling if not well controlled. Fear of becoming disabled and dependent, uncertainty about the disease process, altered body image, devaluation of self, frustration, and depression are common psychosocial problems. Physical limitations caused by disease may limit ADLs. These limitations result in role changes in the family and society. For example, the person may not be able to cook for the family or be an active sexual partner. In addition, extreme fatigue often causes patients to desire an early bedtime and may result in a reluctance to socialize.

Body changes caused by joint changes and steroid therapy (if used) may also cause poor self-esteem and body image.

Because many societies value people with physically fit, attractive bodies, the patient with RA may be embarrassed to be seen in public places. The patient may grieve or experience degrees of depression. He or she may have feelings of helplessness caused by a loss of control over a disease that can "consume" the body. Fortunately, newer drugs have improved the treatment of RA and provide the patient with hope and better disease control.

Living with a chronic disease and its pain is difficult for the patient and family. Patients may experience a loss of control and independence, especially if they are older than 65 years. Chronic suffering affects quality of life. Assess their emotional and mental status in relation to the disease and its problems. Evaluate their support systems and resources. Patients who are knowledgeable about their disease and treatment options feel emotionally stronger to cope with their disease and better able to discuss treatment options with their physician.

Laboratory Assessment

Laboratory tests help support a diagnosis of RA, but no single test or group of tests can confirm it. **Chart 20-8** summarizes the most common laboratory tests that the health care provider uses for diagnosing connective tissue diseases.

The test for *rheumatoid factor (RF)* measures the presence of unusual antibodies of the immunoglobulins G (IgG) and M (IgM) types that develop in a number of connective tissue diseases. Many patients with RA have a positive titer, but not all positive results indicate the disease, *especially in older adults* (Pagana & Pagana, 2010).

The *antinuclear antibody (ANA)* test measures the titer of unusual antibodies that destroy the nuclei of cells and cause tissue death in patients with autoimmune disease. The fluorescent method is sometimes referred to as *FANA*. If this test result is positive (a value higher than 1:40), various subtypes of this antibody are identified and measured. ANA is often negative until later in the disease process and is positive in only 30% of patients with RA (Pagana & Pagana, 2010). It is more commonly positive in other rheumatic diseases, such as systemic lupus erythematosus and scleroderma.

When RA patients also have Sjögren's syndrome or if the syndrome occurs as a separate disease, several unusual anti-SS antibody types may be present. In particular, *anti-SS-A (Ro)* is positive in about 75% of those with RA or those with secondary Sjögren's with RA. The higher the titer of anti-SS antibodies, the more likely that Sjögren's syndrome is present (Pagana & Pagana, 2010).

Serum *complement*, especially C3 and C4, are usually decreased in autoimmune diseases, including RA and lupus. An elevated *erythrocyte sedimentation rate (ESR)*, or "sed rate," can confirm inflammation or infection anywhere in the body. An elevated ESR helps confirm a diagnosis of an unspecified inflammatory disease. The test is most useful to monitor the course of a disease, especially for inflammatory autoimmune diseases. In general, the more severe the disease gets, the higher the ESR rises; as the disease improves or goes into remission, the ESR level decreases.

The *high-sensitivity C-reactive protein*, or *hsCRP*, is another useful test to measure inflammation and may be done with or instead of the ESR. As the name implies, it is more sensitive to inflammatory changes than the ESR. It is also very useful for detecting infection anywhere in the body.

CHART 20-8 LABORATORY PROFILE

Connective Tissue Disease

TEST	NORMAL RANGE FOR ADULTS	SIGNIFICANCE OF ABNORMAL FINDINGS
Rheumatoid factor	Negative	Positive or increase indicative of possible RA or other CTD; may also be elevated in leukemia, liver disease, and renal disease
ANA (total)	Negative (if positive, types of ANA identified [e.g., anti-ENA, anti-Smith, anti-ss-A (Ro)] to indicate what part of cells are involved)	Elevations common in SLE, SSc, RA, and other inflammatory CTDs (5% of healthy adults have positive ANA results)
Serum complement	Total: 75-160 units/mL (C3: 55-120 mg/dL; C4: 20-50 mg/dL)	Decreased values indicative of active autoimmune disease, such as SLE, and other problems like anemia, infection, and malnutrition
Erythrocyte sedimentation rate (ESR)	Male: up to 15 mm/hr Female: up to 20 mm/hr	Increased in inflammatory diseases, like RA, SLE, PMR, temporal arteritis; also elevated in patients with bacterial infections or severe anemias
SPEP	Total: 6.4-8.3 g/dL	
Albumin	3.5-5.0 g/dL	Decreased level occurs with chronic inflammation or infection; also decreased in malnutrition and advanced cirrhosis
Globulin		
Alpha ₁ globulin	0.1-0.3 g/dL	Increased level possible in RA
Alpha ₂ globulin	0.6-1.0 g/dL	
Beta globulin	0.7-1.1 g/dL	
Gamma globulin	0.8-1.6 g/dL	Increased levels indicative of CTD (inflammatory type)
HLA testing (HLA-B27)	None	Presence of HLA-B27 indicative of Reiter's syndrome or ankylosing spondylitis

ANA, Antinuclear antibody; CTD, connective tissue disease; HLA, human leukocyte antigen; PMR, polymyalgia rheumatica; RA, rheumatoid arthritis; SLE, systemic lupus erythematosus; SPEP, serum protein electrophoresis; SSc, systemic sclerosis.

The presence of most chronic diseases usually causes mild to moderate anemia, which contributes to the patient's fatigue. Therefore monitor the patient's complete blood count (CBC) for a low hemoglobin, hematocrit, and red blood cell (RBC) count. An increase in white blood cell (WBC) count is consistent with an inflammatory response. A decrease in the WBC count may indicate Felty's syndrome, a complication associated with late RA. Thrombocytosis (increased platelets) can also occur in patients with late RA. Additional laboratory tests may be performed depending on the body systems and organs that may be affected by the disease. For example, if heart involvement is suspected, the health care provider may request cardiac enzymes.

Other Diagnostic Assessment

A standard x-ray is used to visualize the joint changes and deformities typical of RA. A CT scan may help determine the presence and degree of cervical spine involvement.

An *arthrocentesis* is an invasive procedure that may be used for patients with joint swelling caused by excess synovial fluid (effusion). It may be performed at the bedside or in a physician's office or clinic. After administering a local anesthetic, the physician inserts a large-gauge needle into the joint (usually the knee) to aspirate a sample of synovial fluid to relieve pressure. The fluid is analyzed for inflammatory cells and immune complexes, including RF. Fluid from patients with RA shows increased WBCs, cloudiness, and volume.

Teach the patient to use ice and rest the affected joint for 24 hours after arthrocentesis. Often the health care provider will recommend acetaminophen as needed for pain. If increased pain or swelling occurs, teach the patient or family to notify the health care provider.

NURSING SAFETY PRIORITY**Action Alert**

After an arthrocentesis, monitor the insertion site for bleeding or leakage of synovial fluid. Notify the health care provider if either of these problems occurs.

A bone scan or joint scan can also assess the extent of joint involvement. MRI may be performed to assess spinal column disease or other joint involvement.

Because RA can affect multiple body systems, tests to diagnose specific systemic manifestations are performed as necessary. For example, electromyography helps confirm peripheral neuropathy. Pulmonary function tests help determine the presence of lung involvement.

NCLEX EXAMINATION CHALLENGE**Physiological Integrity**

Which assessment findings will the nurse expect for the client with late-stage rheumatoid arthritis? **Select all that apply.**

- A. Heberden's nodes
- B. High erythrocyte sedimentation rate (ESR) values
- C. Positive antinuclear antibody (ANA) titer
- D. Subcutaneous nodules
- E. Anemia
- F. Red, swollen joints

INTERVENTIONS

As in other types of arthritis, the interdisciplinary health care team manages pain by using a combination of pharmacologic and nonpharmacologic measures. A **synovectomy** to remove

inflamed synovium may be needed for joints like the knee or elbow. Total joint arthroplasty (TJA) may be indicated when other measures fail to relieve pain. TJA is discussed in the Osteoarthritis section.

Managing Inflammation and Pain

Drug therapy and nonpharmacologic interventions are used to manage systemic inflammation and joint pain. The expected outcome is that the disease goes into remission and its progression slows.

Drug Therapy. Some drugs prescribed for RA have anti-inflammatory and/or analgesic actions. Other drugs are immunosuppressive and disease modifying, which may cause remission of the illness and prevent erosive joint changes. Biological response modifiers make up the newest class of disease-modifying drugs that help reduce signals for the immune system to cause inflammation (Chart 20-9). Patients with inflammatory diseases other than RA are also using various biological response modifying medications successfully. Future genetic research will further advance these medications to give even better control of autoimmune diseases. Although RA is a chronic disease and no cure is yet available, drugs now used can better control the disease and prevent further deterioration.

The health care provider, usually a rheumatologist, makes decisions about appropriate drug therapy for patients with rheumatoid disease based on the severity of the disease. Initially, most patients are managed with **disease-modifying antirheumatic drugs (DMARDs)**. As the name implies, these drugs are given to slow the progression of the disease.

Disease-Modifying Antirheumatic Drugs. Methotrexate (MTX) (Rheumatrex), an immunosuppressive medication, in a low, once-a-week dose (generally 25 mg or less per week) has become the mainstay of therapy for RA because it is effective and relatively inexpensive. It is a slow-acting drug, taking 4 to 6 weeks to begin to control inflammatory joint symptoms. Observe for desired drug effects, such as a decrease in joint pain and swelling.

Monitor patients for potential adverse effects, such as decreasing WBCs and platelets (as a result of bone marrow suppression) or elevations in liver enzymes or serum creatinine. *Patients taking MTX are at risk for infection. Teach them to avoid crowds and people who are ill. Remind patients to avoid alcoholic beverages while taking MTX to prevent liver toxicity. Teach them to observe and report other side and toxic effects, which include mouth sores and acute dyspnea from pneumonitis.* Rarely, lymph node tumor (lymphoma) has been associated in those who have RA and are taking MTX. Folic acid, one of the B vitamins, is often given to those who are taking MTX to help decrease some of the drug's side effects.

Pregnancy is not recommended while taking methotrexate because birth defects are possible. *Strict birth control is recommended for childbearing women who are in need of MTX to control their RA.* If pregnancy is ever desired, instruct the patient to consult the rheumatologist as well as an obstetric/gynecologic (OB/GYN) health care provider. Generally, the health care provider will discontinue the drug at least 3 months before planned pregnancy. MTX may be restarted after birth if the patient does not breast-feed.

Leflunomide (Arava) may be prescribed for some patients. It is a slow-acting immune-modulating medication that helps diminish inflammatory arthritis symptoms of joint swelling

and stiffness and improves mobility. The drug is generally prescribed as follows: a loading dose of 100 mg daily for 3 days followed by 20 mg daily thereafter. Inform the patient that Arava takes 4 to 6 weeks and sometimes up to 3 months before maximum benefit is realized.

Arava is a potent medication that is generally tolerated, but side effects of hair loss, diarrhea, decreased WBCs and platelets, or increased liver enzymes have been reported. *Teach patients to report these changes and monitor laboratory results carefully. Remind them to avoid alcohol. Inform them that Arava can cause birth defects, and therefore recommend strict birth control to women of childbearing age. Tell patients to contact the health care provider immediately if pregnancy occurs while taking the drug.* Cholestyramine (Questran) is available to help block the drug's action.

Another DMARD used for RA is hydroxychloroquine (Plaquenil). This drug slows the progression of mild rheumatoid disease before it worsens (see Chart 20-9). It is an anti-malarial drug that helps decrease joint and muscle pain. Patients generally tolerate Plaquenil quite well. In a few cases, mild stomach discomfort, light-headedness, or headache has been reported.

! NURSING SAFETY PRIORITY

Drug Alert

The most serious adverse effect of Plaquenil is retinal damage. Teach patients to report blurred vision or headache. Remind them to have an eye examination every 6 months to detect changes in the cornea, lens, or retina. If this rare complication occurs, the health care provider discontinues the drug.

Nonsteroidal Anti-inflammatory Drugs. NSAIDs are sometimes used for inflammatory arthritis to relieve pain and inflammation (see Chart 20-9). The choice of which one to prescribe depends on the patient's needs and tolerance, as well as the scientific evidence supporting the drug therapy. To decrease GI problems, the NSAID may be given with an H₂-blocking agent, such as ranitidine (Zantac) or misoprostol (Cytotec). If there is no clinical change after 6 to 8 weeks, the health care provider may discontinue the current NSAID and try another one or change to a different drug class.

It was once thought that Celecoxib (Celebrex), a COX-2 inhibiting NSAID, should be given rather than the older NSAIDs like ibuprofen. However, all COX-2 inhibiting drugs have recently been associated with cardiovascular disease, such as myocardial infarction, and some have been taken off the market. The risk for GI bleeding is also high in patients taking Celebrex, and the drug cannot be given to those who have recent open heart surgery.

Biological Response Modifiers. As a group, **biological response modifiers (BRMs)**, sometimes called **biologics**, are one of the newest classes of DMARDs. Most BRMs neutralize the biologic activity of tumor necrosis factor—alpha (TNFA) by inhibiting its binding with TNF receptors. Any one of the BRMs may be tried. If one drug is not effective, the health care provider prescribes another drug in the same class. All these drugs are extremely expensive at this time, and insurance companies may not completely pay for their use. Some patients receive one of these drugs in addition to the drugs in this Drug Therapy section.

Patients with multiple sclerosis or tuberculosis are not given TNF inhibitors. Determine whether the patient has had

CHART 20-9 COMMON EXAMPLES OF DRUG THERAPY

Arthritis and Connective Tissue Disease*

DRUG AND USUAL DOSAGE	PURPOSE OF DRUG	NURSING INTERVENTIONS	RATIONALES
NSAIDs Dosage varies depending on which drug is being used	Relieves chronic pain by inhibiting prostaglandin synthesis	Observe for fluid retention, increased blood pressure, and changes in renal function. Monitor electrolyte and CBC values. Observe for CNS changes (e.g., dizziness or confusion). Instruct patient to have frequent (every 6-12 mo) ophthalmologic examination. Monitor for side effects and toxic effects, including but not limited to nausea/vomiting, bone marrow suppression, and increased liver enzymes. Instruct patient to avoid crowds and people with infections such as influenza. If ill, seek medical attention.	Most NSAIDs cause sodium retention, which can lead to edema, hypertension, renal damage, and heart failure. Drugs should be used with caution in older adults. Most NSAIDs cause increased sodium levels and can cause bone marrow suppression. Most NSAIDs can cause CNS effects, especially in older adults. Drug can cause retinal damage. The side effects and toxic effects of these drugs can be devastating. Immunosuppression increases the risk for infection.
Hydroxychloroquine sulfate (Plaquenil) 200 mg orally daily Immunosuppressive agents (e.g., methotrexate [Rheumatrex] [most commonly used], azathioprine [Imuran], cyclophosphamide [Cytoxan]) Usual dose of oral methotrexate (MTX) is 7.5 to 20 mg/wk. Dosage of other drugs varies depending on disease activity and route of drug administration	An antimalarial agent that helps decrease inflammation and slow disease process Suppresses bone marrow to reduce immune response	Observe for cushingoid changes, such as moon face, buffalo hump, striae, acne, thin skin, bruising, fluid retention, and increased blood pressure. Monitor electrolyte and glucose levels. Monitor weight. Observe for long-term effects of chronic steroid therapy, such as osteoporosis, cataracts, hypertension, diabetes, and impaired healing. Teach patient to increase dietary calcium and vitamin D and to take a supplement. Instruct patient to avoid crowds and persons with infections such as influenza.	These changes are expected and tend to be dose related. Changes diminish as dose decreases. Chronic steroid therapy can cause sodium or fluid retention, potassium depletion, and elevated glucose level. These complications may need to be treated with other drugs or modalities. Drug suppresses immune system (lymphocytes) and increases risk for infection or decreased healing.
Prednisone (Deltasone, Apo-Prednisone ) 10 to 150 mg orally daily, for maintenance, attempt to give dose every other day (to allow patient's adrenal glands to function)	Decreases inflammatory and immune response by decreasing WBC count		

Sulfasalazine (Azulfidine) 500 to 3000 mg orally daily in 2 to 4 doses	Decreases inflammation and slows disease process	Check for sulfa allergy or kidney or liver disease. Teach patient to drink adequate fluids. Teach men that the drug can lower sperm count. Teach patient to have prescribed laboratory tests, usually every 6 to 8 weeks. Avoid alcohol while taking drug. Remind patient to use strict birth control. Do not give BRMs if patient has a serious infection, TB, or MS. Teach patient to report site reaction.	Drug is a sulfa medication that has potential renal/liver toxicities. Failure to drink fluids may cause formation of urine crystals. Low sperm count may interfere with ability to conceive. Increased liver enzymes and decreased blood count have been reported. Alcohol can increase liver enzymes. Drug can cause birth defects. Drugs may exacerbate infections, MS, or lupus. Site reactions can be painful.
Leflunomide (Arava) 10 to 20 mg orally daily	Decreases inflammation by inhibiting an enzyme	Refrigerate all BRMs except Remicade. Teach patient to report chest pain or difficulty breathing during infusion; monitor blood pressure. Teach patients to report site reaction.	Refrigeration prevents drug decomposition. These are potentially life-threatening adverse drug events. Site reactions may occur.
Biological response modifiers (BRMs): <i>Etanercept (Enbrel)</i> : Usually 25 mg subcutaneously weekly <i>Infliximab (Remicade)</i> : Varies from 200 to 400 mg IV every 2 mo <i>Adalimumab (Humira)</i> : 40 mg subcutaneously every 2 wk with MTX or every week with no MTX <i>Anakinra (Kineret)</i> : Typically 100 mg subcutaneously daily	Neutralize biologic activity of either TNF or IL to decrease immune response	Teach patient to monitor site for reaction. Monitor WBC count. Report cough, dizziness, and sore throat. Monitor for dyspnea, wheezing, flushing, itching. Observe for infusion reaction as above.	Site reactions may occur. Drug can cause a severe decrease in WBC count and make patient very susceptible to infection. Serious infections can occur. This drug can cause a mild to moderate allergic reaction.
<i>Abatacept (Orencia)</i> : Based on body weight from 500 to 1000 mg IV each week for 3 wks; then every 2 wks <i>Rituximab (Rituxan)</i> : Two 1000-mg IV doses given 2 weeks apart			

CBC, Complete blood count; CNS, central nervous system; IL, interleukin; MS, multiple sclerosis; MTX, methotrexate; NSAIDs, nonsteroidal anti-inflammatory drugs; TB, tuberculosis; TNF, tumor necrosis factor; WBC, white blood cell.

*This is not a comprehensive list; this chart lists only the common drugs used for arthritis and connective tissue disease.

a recent negative purified protein derivative (PPD) test. If not, a PPD skin test is typically administered and the selected BRM is not started until the results are known to be negative. Collaborate with the health care provider to ensure that this process is complete.

Etanercept (Enbrel) is given subcutaneously either as 50 mg once weekly or as 25 mg twice weekly. Immunosuppression with medications such as methotrexate is generally tried before using Enbrel or other biological response modifiers. Methotrexate may also be continued in combination with biologic therapies because the combination may be more effective than either drug alone. Most patients tolerate Enbrel or Enbrel and methotrexate together; however, laboratory monitoring is important. Combination therapy requires CBC, serum creatinine, and a liver panel to be drawn regularly, generally every 4 to 8 weeks. In general, clinical outcomes with Enbrel have been excellent.

Teach the patient or family member how to self-administer Enbrel injections. Injection site reactions and infections (especially respiratory) are possible adverse effects. Ice and hydrocortisone 1% cream can be used if a red, itchy rash at the injection site develops. The drug manufacturer cannot yet predict long-term potential side effects regarding severity of infection or cancer risk. To date, what has been seen is mild increase in upper respiratory infections with occasional serious infections. Teach the patient to notify the health care provider if infection or a delay in wound healing occurs.

Infliximab (Remicade), first approved to treat Crohn's disease, is given in a single IV infusion over several hours. The initial dose generally used for RA is 3 mg/kg of body weight. After the first few weeks of therapy, the drug is repeated at intervals between 2 and 8 weeks, depending on the response of the patient. Patients typically take methotrexate before starting Remicade and continue on combination therapy.

! NURSING SAFETY PRIORITY

Drug Alert

Teach the patient to report and observe for symptoms of infusion reaction: chest discomfort, tachycardia, shortness of breath, or lightheadedness. If any of these symptoms are reported, decrease the IV rate or discontinue it!

The symptoms of infusion reaction generally subside, but the physician must be notified in case medical assistance is needed. Dose, rate, and interval changes may be needed. Acetaminophen and Benadryl are medications often given before the start of Remicade and are often used at the time of reported infusion reaction. Those who experience serious adverse effects, such as hypertension or anaphylaxis, require permanent discontinuation of the drug.

Adalimumab (Humira) is the first fully human TNFA inhibitor. It is a 40-mg, once every 2 weeks, subcutaneous injection. Symptoms of inflammatory arthritis tend to decrease with the use of Humira, including less joint swelling, less stiffness, and better movement.

Injection site reactions and adverse effects similar to the other TNFA inhibitors have been reported. Careful monitoring, especially with combination therapy of Humira and methotrexate or other immunosuppressive medication, is important and similar to combination therapy with other BRMs.

Anakinra (Kineret) is another biological response modifier. Instead of affecting tumor necrosis factor (TNF), however, it works to inhibit a different protein signal of the immune system called *interleukin-1 (IL-1)*. IL-1 is also a pro-inflammatory protein that signals the immune system to increase inflammation. It is thought that IL-1 is a weaker protein than TNF, but having an alternative drug that targets a different receptor site is helpful when a patient cannot take other biologics. Those who have multiple sclerosis or tuberculosis cannot take TNF inhibitors, but Kineret can be used with this population.

Injection site reactions occur more often with Kineret compared with other BRMs. Ice and hydrocortisone 1% cream are recommended. Remind patients to rotate injection sites. Kineret is administered with a simple jet for self-administration. The patient has the option to use the simple jet or administer the subcutaneous injection traditionally.

Abatacept (Orencia) and *rituximab (Rituxan, MabThera)* require IV infusions every 2 weeks to start and then may be more spread out, depending on the drug. Like the results of the other BRMs, patients usually report feeling a benefit from these drugs in 2 weeks, but it may take months for the maximum benefit to be seen. *Golimumab (Simponi)* is the first biologic that is administered only once each month for both RA and psoriatic arthritis.

The newest biologic that has been approved in the United States is *tocilizumab (Actemra)* and is given when the patient cannot tolerate other drug classes. Tocilizumab is different from other biologics because it is the first humanized interleukin-6 (IL-6) receptor-inhibiting monoclonal antibody that is available for patients with RA. It can be used alone or in combination with other DMARDs. Teach patients about adverse drug effects, including hypertension, GI distress, infection, and an increase in low-density lipoproteins (LDLs) and liver enzymes.

Other Drugs. A few drugs may be given as adjuncts to or instead of the previously described drugs. It is not unusual for a patient to be taking several disease-modifying drugs, such as methotrexate, a BRM, and an adjunct medication. Each drug works differently to relieve symptoms and slow the progression of the disease.

Glucocorticoids (steroids)—usually prednisone (Deltasone)—are given for their fast-acting anti-inflammatory and immunosuppressive effects. Prednisone may be given in high dose for short duration (**pulse therapy**) or as a low chronic dose. Moderate-dose, short-term tapering bridge therapy may be used when inflammation is symptomatic and other RA medications are insufficient or have not yet had an effect.

Chronic steroid therapy can result in numerous complications, such as diabetes mellitus, infection, fluid and electrolyte imbalances, hypertension, osteoporosis, and glaucoma. Some drug effects are dose related, whereas others are not. Observe the patient for complications associated with chronic steroid therapy, and report them to the health care provider. For example, if blood pressure becomes elevated or significant laboratory values change, notify the health care provider.

Instruct patients taking chronic steroids to take calcium 1200 to 1500 mg daily plus vitamin D 400 mg daily to help prevent osteoporosis. Bisphosphonate drugs may also be prescribed. Periodic bone density measurements (DEXA scans) are done to monitor for bone loss.

Patients with RA may experience one or a few joints that have more pain and inflammation than the others. Cortisone injections in single joints may be used to relieve local pain and inflammation. Have the patient ice and rest the joint for 24 hours after the procedure. Oral analgesics also are sometimes needed during that time.

Other immunosuppressive agents that may be used are *azathioprine* (Imuran) and *cyclophosphamide* (Cytoxan). Cyclophosphamide is sometimes given specifically to control RA vasculitis. Such immunosuppressive drugs may cause bone marrow suppression and occasionally leukemia or lymphoma. White blood cell counts are expected to decrease 7 to 14 days after the administration of IV cyclophosphamide; therefore laboratory results are closely monitored to ensure safe limits. Hemorrhagic cystitis is a concern more with oral cyclophosphamide. Instruct the patient to drink water and void frequently (about every 2 hours while awake), which dilutes the urine and empties the bladder, thus decreasing opportunity for bladder irritation from residual drug. Hair thinning or loss can be seen with immunosuppressive medications. Cyclophosphamide may also cause sterility; strict birth control is recommended.

A new oral drug, R788, is awaiting FDA approval for use in patients with RA. It is the first in a new class of drugs that block synkinase, an enzyme that triggers inflammation. It is expected to be used for patients who are also taking MTX.

Nonpharmacologic Interventions

Adequate rest, proper positioning, and ice and heat applications are important in pain management. If acute inflammation is present, ice packs may be applied to “hot” joints for pain relief until the inflammation lessens. The ice pack should not be too heavy. At home, the patient can use a small bag of frozen peas or corn as an ice pack.

Heated paraffin (wax) dips may help decrease pain and increase comfort of arthritic hands. Finger and hand exercises are often done more easily after paraffin treatment. To relieve morning stiffness or the pain of late-stage disease, recommend a hot shower rather than a sponge bath or a tub bath. It is often difficult for the patient with RA to get into and out of a bathtub, although special hydraulic lifts and tub chairs may be available. Safety (grab) bars and nonskid tread in the tub or shower floor are important safety features to discuss with all patients. Some older adults prefer using shower chairs and a walk-in shower that does not have a ledge that could cause falls.

Hot packs applied directly to involved joints may be beneficial. Most physical therapy departments have machines that keep hot packs ready anytime they are needed. Teach patients to use the microwave or stovetop heating instructions to warm the heat pack at home. Remind them to follow the instructions given with each heating device used.

Plasmapheresis (sometimes called *plasma exchange*) is an in-hospital procedure prescribed by a health care provider in which the patient's plasma is treated to remove the antibodies causing the disease. Although not commonly done, this procedure may be combined with pulse therapy for patients with severe, life-threatening disease.

Complementary and Alternative Therapies

Some patients may have pain relief from hypnosis, acupuncture, imagery, music therapy, or other technique. Stress

management is also popular as a pain relief intervention. Chapters 2 and 5 discuss these therapies in more detail.

Adequate nutrition is an important part of the management of RA. Obesity should be avoided or treated if present. The inflammatory state may place a greater burden on the metabolism of some essential nutrients. This catabolic state may be related to increased cytokine production, specifically tumor necrosis factor.

According to the National Center for Complementary and Alternative Medicine, some supplements have been found to help decrease inflammation and prevent bone loss and include:

- Calcium supplements to prevent bone loss (should not be taken in excess to prevent kidney stones)
- Cold water fish or fish oil capsules containing omega-3 fatty acids at 2.5 to 5 g daily to reduce inflammation (should not be taken if the patient is taking anticoagulant therapy)
- Gamma-linolenic acid (GLA), an omega-6 fatty acid found in the oils of certain plant seeds, such as primrose and black currant

According to the Arthritis Foundation, no one food causes or cures RA; however, healthy nutrition in general is supported. Refer the patient to the Arthritis Foundation's pamphlet regarding diet and arthritis. Refer him or her to the dietitian for vitamin- and nutrition-specific questions or recommendations. Any herbal or nutrition supplement should be taken under the supervision of a qualified health care provider to prevent adverse events and drug-food or drug-drug interactions.

Other complementary and alternative medicine (CAM) therapies are safe and have been scientifically proven to be effective to help control RA pain for most people. Examples include mind-body therapies, such as relaxation techniques, tai chi, imagery, and spiritual practices (<http://nccam.nih.gov/health/RA>). For information about these techniques, see Chapter 2.

Promoting Self-Management

Although the physical appearance of a patient with severe RA may create the image that ADL independence is not possible, a number of alternative and creative methods can be used to perform these activities. *Do not perform these activities for the patient unless asked. Those with RA do not want to be dependent.* For example, hand deformities often prevent a patient from opening packages of food, such as a box of crackers; however, he or she may prefer to use the teeth to open the crackers rather than depend on someone else.

In the hospital or long-term care facility, a patient may not eat because of the barriers of heavy plate covers, milk cartons, small packages of condiments, and heavy containers. Styrofoam or paper cups may bend and collapse as he or she attempts to hold them. A china or heavy plastic cup with handles may be easier to manipulate. Collaborate with the dietitian to assist with access to food and total independence in eating.

When fine motor activities (e.g., squeezing a tube of toothpaste) become impossible, larger joints or body surfaces can substitute for smaller ones. For example, teach how to use the palm of the hand to press the paste onto the brush. Devices such as long-handled brushes can help patients brush their

hair; dressing sticks can assist with putting on pants. These examples illustrate the need to assess the problem area, suggest alternative methods, and refer the patient to an occupational or physical therapist for special assistive and adaptive devices if necessary.

Managing Fatigue

Nursing interventions depend in part on identifying the factors contributing to fatigue. For example, increases in pain, sleep disturbances, and weakness are positively associated with increased fatigue. Anemia may also be a contributing factor and may be treated with iron (if an iron deficiency anemia is present), folic acid, or vitamin supplements prescribed by the health care provider. Chronic normochromic or chronic hypochromic anemia often occurs in most chronic systemic diseases. Assess for drug-related blood loss, such as that caused by NSAIDs, by checking the stool for gross or occult blood. *Older white women are the most likely to experience GI bleeding as a result of taking these medications. The reason for this trend is not known.*

When fatigue results from muscle atrophy, the health care provider prescribes an aggressive physical therapy program to strengthen muscles and prevent further atrophy. Patients experience increased fatigue when pain prevents them from getting adequate rest and sleep. Measures to facilitate sleep include promoting a quiet environment, giving warm beverages, and administering hypnotics or relaxants as prescribed, if necessary.

In addition to identifying and managing specific reasons for fatigue, determine the patient's usual daily activities and teach principles of **energy conservation**, including:

- Pacing activities
- Allowing rest periods
- Setting priorities
- Obtaining assistance when needed

Chart 20-10 lists specific suggestions for conserving energy and thus increasing activity tolerance.

Enhancing Body Image

Body image may be affected by both the disease process and drug therapy. Steroids can cause a moonfaced appearance, acne, striae, "buffalo humps," and weight gain. Determine the patient's perception of these changes and the impact of the reactions of family and significant others. The most important intervention is communicating acceptance of the patient. When a trusting relationship is established, encourage him or her to express personal feelings.

CHART 20-10 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Energy Conservation for the Patient with Arthritis

- Balance activity with rest. Take one or two naps each day.
- Pace yourself; do not plan too much for one day.
- Set priorities. Determine which activities are most important, and do them first.
- Delegate responsibilities and tasks to your family and friends.
- Plan ahead to prevent last-minute rushing and stress.
- Learn your own activity tolerance, and do not exceed it.

Another way to improve body image while in the hospital or nursing home is to use personal items. A hospital gown reinforces the sick role. Encourage patients to wear their own clothes, to brush their hair, and to use makeup if desired. Assist or teach the family to assist the patient as needed. The use of colored hair accessories, nail polish, and perfume may improve a female's image and self-concept.

As a reaction to body image disturbance and the presence of a chronic, painful disease, some patients display behaviors indicative of loss. They may use coping strategies that range from denial or fear to anger or depression. In an attempt to regain control over the effects of the disease process, they may appear to be "manipulative and demanding" and sometimes may be referred to as having an "arthritis personality." *This personality, which represents a negative label, is a myth; using these terms should be avoided.* Patients are trying to cope with the effects of their illness and should be treated with patience and understanding. Continually assess and accept these behaviors, but remain realistic in discussing goals to improve self-esteem. Emphasize their strengths, and help them identify previously successful coping strategies.

Community-Based Care

Patients with rheumatoid arthritis (RA) are usually managed at home but, in a few cases, may be institutionalized in a long-term care facility if they become restricted to bed or a wheelchair. Some patients may be transferred to a rehabilitation facility for several weeks to aid in developing strategies, techniques, and skills for independent living at home.

Home Care Management

The amount of home care preparation depends on the severity of the disease. Structural changes may be necessary if there are deficits in ADLs or mobility. Doors must be wide enough to accommodate a wheelchair or walker if one is used. Ramps are needed to prevent the patient in a wheelchair from becoming homebound. If the person cannot use stairs, he or she must have access to facilities for all ADLs on one floor. Handrails should be available in the bathroom and halls.

To promote continued homemaking functions, countertops and appliances may require structural changes. The patient may also require handrails and elevated chairs and toilet seats, which facilitate transfers (Fig. 20-6). *These devices are especially important for older adults with arthritis.*

FIG. 20-6 Handrails and an elevated toilet seat make transfers easier for the patient.

Teaching for Self-Management

Health teaching is a vital role for nurses in the diagnosis and management of arthritis. Many people have signs and symptoms of joint inflammation but do not seek medical attention. Teach them to seek professional health care to reduce pain and disability.

Health teaching is also important for promoting adherence to a treatment plan. A patient who understands the disease process and the treatment rationale can better follow and ask questions about the treatment plan.

Teach patients to discuss any questions with their health care provider before trying any over-the-counter or home remedies. Some remedies may be harmful. Check with the Arthritis Foundation for the latest information on arthritis myths and quackery (www.arthritis.org).

Provide information to the patient and family about drug therapy, as well as joint protection, energy conservation, rest, and exercise. This health teaching is summarized in [Charts 20-5, 20-6, and 20-10](#).

Assess the patient's coping strategies. The patient with RA often reports being on an "emotional roller coaster" from coping with a chronic illness every day. Control over one's life is an important human need. The patient with an unpredictable chronic disease may lose this control, and this lowers self-esteem. Health care providers must allow the patient to make decisions about care. Families and significant others must also include him or her in decision making. Although the patient's behavior may be perceived as demanding or manipulative, his or her self-esteem cannot be improved without this important aspect of interpersonal relationships.

Increased dependency also affects a sense of control and self-esteem. Some people ignore their health needs and portray a tough image for others by insisting that they need no assistance. Emphasize to the patient and family that asking for help may be the best decision at times to prevent further joint damage and disease progression.

RA may also affect work and social roles. The patient may have physical difficulty doing tasks that require lifting, climbing, grasp, or gross or fine motor activities. The severity of RA disease may cause difficulty with total number of hours worked. Some people with RA can do their jobs well without problem; others may have varying degrees of difficulty. Those who can no longer do their job at work may need to discuss with their employer having a lighter workload, but some may need to file for disability with their company and Social Security.

Arthritis support groups and self-help courses provide the education and the support that patients, families, and friends need. Refer the patient to a psychological counselor or religious or spiritual leader for emotional support and guidance during times of crisis or as needed. Identify and recommend other support systems within the family and community when necessary.

Health Care Resources

The need for health care resources for the patient with RA is similar to that for the patient with osteoarthritis. A home care nurse or aide, physical therapist, or occupational therapist may be needed during severe exacerbations or as the disease progresses. In collaboration with the case manager, identify these resources and make sure they are available before

transfer or discharge. The Arthritis Foundation is an excellent source of information and support.

DECISION-MAKING CHALLENGE

Teamwork and Collaboration; Safety

A 52-year-old woman with RA has been controlled with methotrexate and Celebrex for 10 years. Recently she has experienced increased joint pain and swelling, which have affected her mobility and activity level. Earlier in the week, she fell while walking to her car after she left the bank where she works as a teller. The rheumatologist plans to add adalimumab (Humira) to her drug regimen.

1. What additional nursing assessment is needed for this patient now and why?
2. With what members of the health care team might you collaborate as part of her plan of care?
3. What safety measures are needed before she begins Humira?
4. What health teaching will she need before starting Humira?
5. What options related to her current role at the bank might she have?

LUPUS ERYTHEMATOSUS

Pathophysiology

In the mid-nineteenth century, the facial rash accompanying this disease was thought to look like the facial markings of a wolf. The rash was usually red, and thus the term *erythematosis*, a Latin word meaning "reddened," was added to describe the disease.

The two main classifications of lupus are discoid lupus erythematosus (DLE) and systemic lupus erythematosus (SLE). A small percentage of patients with lupus have the DLE type, which affects only the skin.

Unlike DLE, **systemic lupus erythematosus** is a chronic, progressive, inflammatory connective tissue disorder that can cause major body organs and systems to fail. It is characterized by spontaneous remissions and **exacerbations** ("flare-ups"), and the onset may be acute or insidious (slow). The condition is potentially fatal, but the survival rate has improved dramatically when SLE is diagnosed early and treated adequately. Today most patients with SLE are living many years after diagnosis and can lead productive lives. Improvements in determining the cause, diagnosis, and treatment of lupus account for the prolonged survival.

Lupus is thought to be an autoimmune process. Antinuclear antibodies (ANAs) primarily affect the DNA, ribonucleic acid (RNA), and other components within the cell nuclei. As a result, immune complexes form in the serum and organ tissues, which cause inflammation, damage, and destruction (McCance et al., 2010). These complexes invade organs directly or cause **vasculitis** (vessel inflammation), which deprives the organs of arterial blood and oxygen.

Autoimmune complexes in SLE tend to be most attracted to the glomeruli of the kidneys. Therefore many of these patients have some degree of kidney involvement, called *lupus nephritis*—the leading cause of death. Other causes of death from the disease are cardiac and central nervous system involvement.

The onset of the disease occurs most often during the childbearing years (ages 20 to 40 years), but it has been reported in young children and older adults. A genetic predisposition is based on the trend to develop the disease in

CULTURAL AWARENESS

Lupus affects women 10 times more often than men; women of color are affected far more often than Euro-Americans. The reason for this difference is unknown (McCance et al., 2020). The disease also occurs among American Indians, Asian Americans, and Hispanics (Lupus Foundation of America, 2011).

some twins and the occurrence of autoimmune disease in some families of patients who have lupus. However, it is not the only basis of the disease. Like RA, lupus is probably caused by a *combination of genetic and environmental factors*.

GENETIC/GENOMIC CONSIDERATIONS

Over the past several decades, more than 100 genetic risk factors have been identified as possible causes of lupus. The research challenge is that patients with lupus differ from each other in their genetic risk and makeup. To complicate this situation, environmental factors can trigger an autoimmune response in some people and not in others with the same risk. For example, SLE may be triggered by a virus, such as Epstein-Barr, in some people who have a genetic risk for the disease (Sestak et al., 2007).

A transient lupus-like syndrome can occur in some patients taking select medications, especially procainamide (Pronestyl) and hydralazine (McCance et al., 2010). When these drugs are discontinued, the syndrome usually resolves. Neither of these drugs is commonly used as much today. Long-term use of newer biological response modifiers (BRMs) like infliximab, which is used to treat RA and other autoimmune diseases, may also cause a lupus-like syndrome.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

It is impossible to describe a typical textbook picture of a patient with lupus because of the extreme range of symptoms. There is no classic presentation of this disease. When lupus is in remission, the patient may appear healthy and have few or no activity limitations. When the disease flares, some patients may be so ill that admission to a critical care unit is needed. [Chart 20-11](#) highlights the clinical manifestations that can occur with systemic lupus.

Physical Assessment/Clinical Manifestations

Skin Involvement. The major skin manifestation of DLE and SLE is a dry, scaly, raised rash on the face (**“butterfly” rash**) ([Fig. 20-7](#)). This rash may also appear on other sun-exposed areas. The rash is initially nonscarring and may increase in a lupus flare and disappear when the disease is in remission.

Individual round **discoid** (coinlike) **lesions** are the scarring lesions of discoid lupus. The lesions are especially evident when the patient is exposed to sunlight or ultraviolet light. Alopecia is also common in lupus. Observe and document all skin changes, and monitor them daily while the patient is in an acute care setting or during an ambulatory care or home visit. Mouth ulcers are not uncommon.

CHART 20-11 KEY FEATURES

Systemic Lupus Erythematosus (SLE) and Systemic Sclerosis (SSc)

SYSTEMIC LUPUS ERYTHEMATOSUS	SYSTEMIC SCLEROSIS
Skin Manifestations	
Inflamed, red rash	Inflamed
Discoid lesions	Fibrotic
	Sclerotic
	Edematous
Renal Manifestations	
Nephritis	Renal failure
Cardiovascular Manifestations	
Pericarditis	Myocardial fibrosis
Raynaud’s phenomenon	Raynaud’s phenomenon
Pulmonary Manifestations	
Pleural effusions	Interstitial fibrosis
	Pulmonary hypertension
Neurologic Manifestations	
CNS lupus	Not common
Gastrointestinal Manifestations	
Abdominal pain	Esophagitis
	Ulcers
Musculoskeletal Manifestations	
Joint inflammation	Joint inflammation
Myositis	Myositis
Other Manifestations	
Fever	Fever
Fatigue	Fatigue
Anorexia	Anorexia
Vasculitis	Vasculitis

CNS, Central nervous system.

FIG. 20-7 The characteristic “butterfly” rash of systemic lupus erythematosus.

Other Manifestations. In addition to skin changes, *polyarthritis* occurs in most patients with SLE. The early joint changes are similar to those seen in rheumatoid arthritis (RA), but severe deformities are not common even in late disease. Small joints and the knees are most commonly involved. **Osteonecrosis** (bone necrosis from lack of oxygen) is often seen in those who have been treated for at least 5 years with steroids like prednisone. Chronic steroid therapy may cause the constriction of small blood vessels supplying the joint, which causes the tissue to die. The hip is most commonly affected, and reports of pain and decreased mobility result. As a result, a total hip arthroplasty may be done.

Observe for *muscle atrophy*, which can result from disuse, from skeletal muscle invasion by the immune complexes (**myositis**), or from chronic steroid therapy. Myalgia (muscle pain) may also occur. Inspect and palpate the major muscles, especially those in the extremities.

Because SLE is an inflammatory condition, *fever* and *fatigue* are common findings. *Fever is the classic sign of a flare, or exacerbation.* Various degrees of generalized weakness, fatigue, anorexia, and weight loss may occur. These signs may be the only evidence of disease, which makes diagnosis by the health care provider difficult. Therefore some patients have a diagnosis of “probable SLE.”

Any or all body systems may be affected by SLE. Because lupus nephritis is the leading cause of death, carefully assess for signs of renal involvement (e.g., changes in urine output, proteinuria, hematuria, fluid retention).

Pleural effusions or *pneumonia* is found in almost half of all cases of SLE, but this complication is usually not life threatening. Pulmonary restrictive or obstructive changes may not result in overt clinical signs; however, progressive involvement can lead to dyspnea and arterial blood gas abnormalities. Perform a complete respiratory assessment to determine any abnormalities in respiratory pattern or breath sounds.

Pericarditis is the most common cardiovascular manifestation and causes tachycardia, chest pain, and myocardial ischemia. Monitor the vital signs at least every 4 hours while the patient is in the hospital, and report chest pain immediately to the physician. *Anemia, leukopenia, and thrombocytopenia* are also common in patients with SLE.

Raynaud's phenomenon occurs in a small portion of lupus patients. On exposure to cold or extreme stress, the patient reports the characteristic red, white, and blue color changes and severe pain in the digits; these changes are caused by arteriolar vasospasm. Ask patients whether color changes occur when their hands or feet are exposed to cold or when they are extremely stressed.

Neurologic manifestations are varied. Central nervous system effects include psychoses, paresis, seizures, migraine headaches, and cranial nerve palsies. Peripheral neuropathies are also common. Perform a neurologic assessment as described in Chapter 43.

Monitor *abdominal pain*, which usually results from **serositis** (peritoneal involvement). Mesenteric arteritis, pancreatitis from arteritis of the pancreatic artery, and colonic ulcers also can cause abdominal pain with lupus. Jaundice is rare. Many patients have lymph enlargement, and a few have splenomegaly (enlarged spleen). Palpate the lymph nodes, and document findings. Vasculitis affecting any major or small vessels can lead to organ failure.

Psychosocial Assessment

The psychosocial results of lupus can be devastating. With either DLE or SLE, the rash can be disfiguring and embarrassing. Young adult women who never had a blemish are confronted with a rash that cannot be completely covered with makeup. If chronic steroid therapy is used, side effects such as acne, striae, fat pads, and weight gain intensify the problem of an already altered body image.

Chronic fatigue and generalized weakness may prevent the patient from being as active as in the past. He or she may avoid social gatherings and may withdraw from family activities. The unpredictability and chronicity of SLE can cause fear and anxiety. Fear may increase if the patient knows another person with the disease, particularly if the other person has more advanced severe disease. Unfortunately, the myth that lupus is fatal is still common. Inform the patient and family that control of lupus is generally possible with regular medical monitoring, medications, and healthy practices, such as limiting sun exposure to prevent exacerbation of the disease.

Assess the patient's and family's feelings about the illness to identify areas requiring intervention. Determine their usual coping mechanisms and support systems before developing a plan of care. See p. 335 in the Psychosocial Assessment section of the Rheumatoid Arthritis section for additional information.

Laboratory Assessment

Because discoid lupus erythematosus (DLE) is not a systemic condition, the only significant test is a *skin biopsy*. The physician gently scrapes skin cells from the rash for microscopic evaluation. The characteristic lupus cell and a number of inflammatory cells confirm the diagnosis.

Some of the immunologic-based laboratory tests used to diagnose SLE are the same as those performed for rheumatoid arthritis (RA): rheumatoid factor, antinuclear antibody, erythrocyte sedimentation rate, serum protein electrophoresis, serum complement (especially C3 and C4), and immunoglobulins (see Chart 20-8). A false-positive Venereal Disease Research Laboratory (VDRL) syphilis test is common with lupus (Pagana & Pagana, 2010).

More specific immunologic tests, such as anti-SS-a (Ro), anti-SS-b (La), anti-Smith (anti-Sm), anti-DNA, and extractable nuclear antigens (ENAs), are also performed. High titers of some of these antibodies are associated with lupus, but some of these antibodies can be found in people without the disease. Some patients with lupus do not have high titers of these antibodies.

A complete blood count (CBC) commonly shows **pancytopenia** (a decrease of all cell types), probably caused by direct attack of the blood cells or bone marrow by immune complexes. Serum electrolyte levels, renal function, cardiac and liver enzymes, and clotting factors are also routinely assessed to determine other body system functioning.

INTERVENTIONS

The health care provider often prescribes potent drugs that are used topically and systemically. In addition, precautions are taken to prevent further skin impairment and exacerbations. Many of the skin lesions do not disappear, even with treatment, but they usually fade when the disease is in remission.

Managing Lupus with Drug Therapy

With DLE, the patient's major concern is the rash or discoid lesions. Patients with SLE are also concerned about skin changes. Topical cortisone preparations help reduce inflammation and promote fading of the skin lesions. In addition, the health care provider may prescribe the anti-malarial agent *hydroxychloroquine* (Plaquenil) for some patients (see [Chart 20-9](#)). Plaquenil decreases the absorption of ultraviolet light by the skin and therefore decreases the risk for skin lesions. *Teach patients to have frequent eye examinations if they are receiving Plaquenil.*

Acetaminophen (Tylenol) or NSAIDs may be used to treat musculoskeletal problems like arthritis and myalgias. The aim of managing other systemic manifestations of SLE is to treat the disease aggressively until remission.

In addition to medications for skin lesions, the health care provider often prescribes chronic steroid therapy to treat the systemic disease process. For renal or central nervous system lupus, the health care provider may also prescribe immunosuppressive agents, such as methotrexate (Rheumatrex) or azathioprine (Imuran) (see [Chart 20-9](#)). Although clinical manifestations improve during remission, maintenance doses of these drugs are usually continued to prevent further exacerbations of the disease. These drugs make patients susceptible to infections.

! NURSING SAFETY PRIORITY

Drug Alert

When patients are taking steroids and/or immunosuppressants, stress the importance of avoiding large crowds and people who are ill. Teach patients to report any early sign of infection to their health care provider. Observe for side effects and toxic effects of these drugs, and report their occurrence immediately.

For severe renal involvement, immunosuppressants may be given in combination with steroids. For patients who do not respond to this regimen, a high-dose IV bolus of glucocorticoids, cyclophosphamide, and plasmapheresis may be tried for 3 consecutive days. Renal transplantation has been successful for some patients.

Two new drugs in clinical trials show promise for lupus patients—Lupuzor, a new oral drug, and belimumab (Benlysta), a monoclonal antibody (mAb). If approved, these drugs will be the first to be approved in 50 years for managing lupus.

Protecting the Skin

Teach patients to protect their skin to prevent an exacerbation of the disease.

! NURSING SAFETY PRIORITY

Action Alert

Instruct patients to avoid prolonged exposure to sunlight and other forms of ultraviolet lighting, including certain types of fluorescent light. Remind them to wear long sleeves and a large-brimmed hat when outdoors. Patients should use sun-blocking agents with a sun protection factor (SPF) of 30 or higher on exposed skin surfaces.

In addition, teach patients to clean the skin with mild soap (e.g., Ivory) and to avoid harsh, perfumed substances. The skin should be rinsed and dried well and lotion applied.

CHART 20-12 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Evidence-Based Practice for Skin Protection in Patients with Lupus Erythematosus

- Cleanse your skin with a mild soap, such as Ivory.
- Dry your skin thoroughly by patting rather than rubbing.
- Apply lotion liberally to dry skin areas.
- Avoid powder and other drying agents, such as rubbing alcohol.
- Use cosmetics that contain moisturizers.
- Avoid direct sunlight and any other type of ultraviolet lighting, including tanning beds.
- Wear a large-brimmed hat, long sleeves, and long pants when in the sun.
- Use a sun-blocking agent with a sun protection factor (SPF) of at least 30.
- Inspect your skin daily for open areas and rashes.

Excess powder and other drying substances should be avoided. Cosmetics must be carefully selected and should include moisturizers and sun protectors. If desired, refer the patient to a medical cosmetologist who specializes in applying makeup for skin lesions of all types, if requested.

Patients' hair should receive special attention because alopecia (hair loss) is common. Recommend the use of mild protein shampoos and the avoidance of harsh treatments (e.g., permanents or highlights) until the hair regrows during remission.

Community-Based Care

Community-based care for the patient with lupus is similar to that for RA. In general, the patient is home but may need repeated hospitalizations during exacerbations of disease. He or she usually does not need rehabilitation unless having surgery, because severe joint deformity and prolonged immobility are not common in lupus.

Two major differences exist between SLE and RA in terms of education of the patient and family or significant others. First, instruct patients how to protect the skin ([Chart 20-12](#)). Second, teach them to monitor body temperature. Fever is the major sign of an exacerbation, during which they can become seriously ill. Teach the importance of reporting any other unusual or new clinical manifestations to the health care provider immediately.

Many patients become frustrated that family members, significant others, and lay people do not have a thorough understanding of lupus. When lupus is in complete remission, patients appear to be healthy; however, an exacerbation can lead to a critical care admission. This unpredictability disrupts the patient's life and can cause fear and anxiety. Help him or her identify coping strategies and support systems that can help with functioning in the community.

Teach the possible effects of the disease on lifestyle, including fatigue. Women of childbearing age need to know that pregnancy can be a stressor and can cause an exacerbation of the disease, either during pregnancy or after delivery. The pregnant woman also has an increased risk for miscarriage, stillbirth, or premature birth. Pregnancy is not recommended for those with cardiac, renal, or central nervous system involvement. Sexual counseling regarding contraception options may be necessary.

The Arthritis Foundation is a general resource for all patients with connective tissue disease. The Lupus Foundation (www.lupus.org) is a resource specific for patients with lupus. It is a national organization and has chapters in every state to provide information and assistance for patients with lupus and their families. Local support groups and services are offered free of charge.

NCLEX EXAMINATION CHALLENGE

Health Promotion and Maintenance

What health teaching by the nurse is the most important for clients diagnosed with discoid lupus erythematosus and managing the disease using topical steroid cream?

- A. "Take calcium supplements to prevent osteoporosis from the steroid."
- B. "Stay away from crowds and people with infections."
- C. "Avoid being in the sun to prevent disease flare-ups."
- D. "Use heavy powder makeup to cover skin lesions."

SYSTEMIC SCLEROSIS

Pathophysiology

Systemic sclerosis (SSc), also called *scleroderma*, is an uncommon chronic, inflammatory, autoimmune connective tissue disease. Formerly called *progressive systemic disease*, or *PSS*, this illness is not always progressive. **Scleroderma** means hardening of the skin, which is only one clinical manifestation of the problem. Some patients, often children, have only skin involvement, or localized scleroderma (also called *linear scleroderma*). However, adults usually have skin and other body system involvement. SSc is less common than systemic lupus erythematosus (SLE) but is associated with a higher mortality rate. See [Chart 20-11](#) for a comparison of the clinical manifestations of these two diseases. The manifestations for both diseases vary widely from person to person.

The early inflammatory process of SSc is so similar to that of lupus that patients may first be diagnosed as having probable SLE until the disease progresses or until antibody testing supports the diagnosis. The inflamed tissue in patients with SSc becomes fibrotic and then **sclerotic** (hard). Renal involvement is the leading cause of death. Respiratory involvement and hypertension are also common. Patients with SSc do not respond well to the steroids and immunosuppressants used for lupus, and therefore the mortality rate is higher.

The classification for systemic sclerosis is:

- **Diffuse cutaneous SSc**—skin thickening on the trunk, face, and proximal and distal extremities (over most of the body)
- **Limited cutaneous SSc**—thickened skin limited to sites distal to the face, neck, and distal extremities

Patients with the *limited* form of the disease often have the **CREST syndrome**:

- Calcinosis (calcium deposits)
- Raynaud's phenomenon (first symptom that occurs)
- Esophageal dysmotility
- Sclerodactyly (scleroderma of the digits)
- Telangiectasia (spider-like hemangiomas)

The first symptom that usually occurs in patients with the *diffuse* form of the disease is hand and forearm edema, which may exist with bilateral carpal tunnel syndrome.

Gastroesophageal reflux disease (GERD) is commonly present in patients with either type of the disease.

Little is known about the cause of SSc, but autoimmunity is suspected. The occurrence of more than one case per family is uncommon, but other connective tissue diseases may be noted in the family history. At this time, specific genetic causes have not been confirmed.

Systemic sclerosis has been described in people of all races and in all geographic areas and affects over 300,000 people. Women are affected more often than men. The onset of the disease is usually between 25 and 55 years of age, with most women getting it in their 40s (Scleroderma Foundation, 2011).

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Physical Assessment/Clinical Manifestations

Arthralgia (joint pain) and stiffness are common manifestations that you can assess during the musculoskeletal examination. The acute inflammation that occurs with rheumatoid arthritis (RA) is not common, and deformities are rare.

Findings on inspection of the skin depend on the stage of the scleroderma. Typically, a painless, symmetric, pitting edema of the hands and fingers is present, especially in patients with the diffuse form of the disease. The edema may progress to include the entire upper and lower extremities and face. In this phase, the fingers are described as *sausage-like*. The skin is taut, shiny, and free of wrinkles. If diffuse scleroderma occurs, swelling is replaced by tightening, hardening, and thickening of skin tissue; this phase is sometimes called the *indurative phase* ([Fig. 20-8](#)). The skin loses its elasticity, and range of motion is markedly decreased; ulcerations may occur. Joint contractures may develop, and the patient may be unable to perform ADLs independently.

Major organ damage is likely to develop with diffuse scleroderma, specifically affecting the renal and cardiopulmonary systems. The initial GERD symptoms progress into other problems, especially affecting the esophagus. The esophagus loses its motility, resulting in *dysphagia* (*difficulty swallowing*). Assess for the ability of the patient to swallow before allowing him or her to drink or eat food. A small, sliding hiatal hernia may be present, and swallowing may be difficult. Reflux of the gastric contents can cause esophagitis and subsequent ulceration, particularly in the lower two thirds of the esophagus. Intestinal changes are similar to those of the esophagus. Peristalsis is diminished, which causes clinical manifestations similar to a partial bowel obstruction. Malabsorption is a common complication, causing malodorous *diarrheal stools*.

In addition to assessing problems of the digestive tract, observe for *cardiovascular manifestations*. *Raynaud's phenomenon* occurs in various degrees in most patients with SSc. On exposure to cold or emotional stress, the small arterioles in the digits of both hands and feet rapidly constrict, which causes decreased blood flow. In severe cases, the patient experiences digit necrosis, excruciating pain, and **autoamputation of the distal digits** (the tips of the digits fall off spontaneously). In many patients, vasculitic lesions, often around the nail beds (**periungual lesions**), are evident. *Myocardial fibrosis*, another common problem, is evidenced by

FIG. 20-8 Late-stage skin changes seen in patients with systemic sclerosis.

electrocardiographic (ECG) changes, cardiac dysrhythmias, and chest pain.

Lung involvement in the patient with SSc may go undetected until late in the disease or sometimes until autopsy. *Fibrosis of the alveoli and interstitial tissues* is present in almost all cases of the disease, but clinical manifestations may not be present. Patients with scleroderma and *pulmonary arterial hypertension* have a more serious prognosis. *Renal involvement* is an important aspect of the overall disease process and often causes malignant hypertension and death. Assess for signs of impending organ failure, such as changes in urine output and increased blood pressure.

Laboratory Assessment

The laboratory findings for SSc are similar to those for SLE. Clinical findings and the patient's response to drug therapy help the health care provider differentiate between the two diseases. Additional tests depend on which organs seem to be affected. Upper and lower GI series are commonly performed because of the frequency of GI clinical manifestations.

INTERVENTIONS

The medical management of SSc aims to force the disease into remission and thus slow disease progression. The health care provider uses drug therapy primarily for this purpose, but it is often unsuccessful. Systemic steroids and immunosuppressants are used in large doses and often in combination (see [Chart 20-9](#)). Another desired outcome of disease management is to identify early organ involvement and treat it before it becomes severe and irreversible. For example, a patient who has lung involvement receives aggressive respiratory therapy and other treatments as the condition requires. Recently, bosentan (Tracleer), the first of a new class of drugs called *endothelin receptor antagonists*, demonstrated improved walk tests for patients with class III or class IV pulmonary arterial hypertension. Various doses improved patients' breathing during exercise, but the potential for liver injury at the highest dose caused recommended doses to be lowered. Teach the patient the desired and potential adverse effects, including liver toxicity and birth defects. Remind him or her of the importance of follow-up testing for liver enzyme levels.

Local skin protective measures can help maintain skin integrity. Teach the patient to use mild soap and lotions and gentle cleaning techniques. Inspect the skin for further

CHART 20-13 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

The Patient with Systemic Sclerosis and Esophagitis

- Keep the patient's head elevated at least 60 degrees during meals and for at least 1 hour after each meal.
- Provide small, frequent meals rather than three large meals each day.
- Give the patient small amounts of food for each bite, and explain the importance of chewing each bite carefully before swallowing.
- Provide semisoft foods, such as mashed potatoes and pudding or custard; liquids are most likely to cause choking.
- Collaborate with the dietitian about the patient's diet.
- Teach the patient to avoid foods that increase gastric secretion, such as caffeine, pepper, and other spices.
- Give antacids or histamine antagonists as needed.

changes or open lesions. Skin ulcers are treated according to their type and location.

In addition to drug therapy to control the overall disease process, specific measures can provide comfort. The patient with SSc not only experiences chronic joint pain but also has severe, acute pain during episodes of Raynaud's phenomenon. Remind unlicensed nursing personnel to use a bed cradle and foot board to keep bed covers away from the skin in severe cases. Adjust the room temperature to prevent chilling, which can precipitate digit vasospasm. The patient who can tolerate touching of the affected areas can wear gloves and socks to increase warmth. Because cigarette smoking and extreme emotional stress can also cause symptoms to recur, teach the patient to avoid or minimize these factors as much as possible.

If the patient has esophageal involvement, collaborate with the speech and language pathologist to schedule a swallowing study. The patient may need small, frequent meals rather than the traditional three meals daily. He or she should minimize the intake of foods and liquids that stimulate gastric secretion (e.g., spicy foods, caffeine, alcohol). Teach the patient to keep his or her head elevated for 1 to 2 hours after meals. He or she may need to be in this position continuously. Histamine antagonists and antacids help reduce and neutralize gastric acid. To help prevent choking, collaborate with the dietitian for dietary changes ([Chart 20-13](#)).

Nursing care for the patient with joint pain and decreased mobility is very similar to that for rheumatoid arthritis (see the Interventions section of the Rheumatoid Arthritis section on p. 336). NSAIDs are given for inflammation and pain. Joint protection and energy conservation are also important for these patients.

Community-Based Care

Community-based care for the person with SSc is similar to that for lupus. The patient is treated at home but may need frequent hospitalizations if major organ involvement occurs during exacerbations. The Arthritis Foundation (www.arthritis.org) and Scleroderma Foundation (www.scleroderma.org) are excellent resources for more information about the disease and how to manage it.

GOUT

Pathophysiology

Gout, or gouty arthritis, is a systemic disease in which urate crystals deposit in the joints and other body tissues, causing inflammation. It is the most common inflammatory arthritis in older adults, affecting an estimated 6 million people (Arthritis Foundation, 2011a). The cause and treatment of gout have been firmly established. The classic case of well-advanced disease is seldom seen today unless the patient does not adhere to the therapeutic regimen. The two major types of gout are primary and secondary.

Primary gout is the most common type and results from one of several inborn errors of purine metabolism. An end product of purine metabolism is uric acid, which is usually excreted by the kidneys. In primary gout, the production of uric acid exceeds the excretion capability of the kidneys. Sodium urate is deposited in synovium and other tissues, resulting in inflammation. For some patients, primary gout is inherited as an X-linked trait; males are affected through female carriers. A number of patients have a family history of gout. Primary gout affects middle-aged and older men and postmenopausal women. The peak time of onset in men is between 40 and 50 years of age (McCance et al., 2010).

Secondary gout involves **hyperuricemia** (excessive uric acid in the blood) caused by another disease or factor. Secondary gout affects people of all ages. Renal insufficiency, diuretic therapy, “crash” diets, and certain chemotherapeutic agents decrease the normal excretion of uric acid and other waste products. Disorders such as multiple myeloma and certain carcinomas result in increased production of uric acid because of a greater turnover of cellular nucleic acids. Treatment involves management of the underlying disorder.

Hyperuricemia and gout are often seen in older patients with cardiovascular health problems. There is some debate as to whether gout actually contributes to the development of coronary artery disease (CAD). The exact cause of this relationship needs further study.

The three clinical stages of the primary disease process are asymptomatic hyperuricemia, acute gouty arthritis, and chronic or tophaceous gout (McCance et al., 2010). The patient is usually unaware of the *asymptomatic hyperuricemic stage* unless he or she has had a serum uric acid level determination. The serum level is elevated, but no obvious

signs of the disease are present. No treatment is needed in this stage.

The first “attack” of gouty arthritis begins the *acute stage*. The patient experiences excruciating pain and inflammation in one or more small joints, usually the metatarsophalangeal joint of the great toe, called **podagra**. The erythrocyte sedimentation rate (ESR) is usually increased as a result of the inflammatory process. Months or years may pass before additional attacks occur. The patient is asymptomatic, and no abnormalities are found during examination of the joints.

After repeated episodes of acute gout, deposits of urate crystals develop under the skin and within the major organs, particularly in the renal system. The patient is then classified as having *chronic tophaceous gout*. In chronic gout, urate kidney stone formation is more common than renal insufficiency. Chronic gout can begin anywhere between 3 and 40 years after the initial gout symptoms occur (McCance et al., 2010).

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Note the patient’s age, gender, and family history of gout. A complete history is needed to determine whether gout has been caused by another problem. Some women overuse diuretics, which can lead to secondary gout.

Acute Gout

Overt manifestations are present in the acute and chronic phases of gout. You will likely encounter a patient with acute gout, but chronic gout is not as common in the United States today. *Joint inflammation is the most common finding and is usually so painful that the patient seeks medical care immediately.* Inspect the inflamed area. It is usually too painful and swollen to be touched or moved.

The health care provider requests a serum uric acid level to check for hyperuricemia. Because the level can be altered by food intake, several measurements may be obtained. A consistent level of more than 6.5 mg/dL is generally considered abnormal. Urinary uric acid levels are also measured; an overproduction of uric acid is confirmed by an excretion of more than 750 mg/24 hr (Pagana & Pagana, 2010).

The health care provider may request renal function tests, such as blood urea nitrogen (BUN) and serum creatinine levels, to monitor possible kidney involvement. A definitive diagnostic test for the disease is synovial fluid aspiration (arthrocentesis) to detect the needle-like crystals in the affected joint that are characteristic of the disorder.

Chronic Gout

With chronic gout, inspect the skin for **tophi**, or deposits of sodium urate crystals (Fig. 20-9). Although tophi may occur anywhere, they commonly appear on the outer ear. Other common sites for tophi are the arms and fingers near the joints. The tophi are hard on palpation and are irregular in shape. When the skin over the tophi is irritated, it may break open and a yellow, gritty substance is discharged. Infection may result.

Other manifestations of chronic gout include signs of renal calculi (stones) or renal dysfunction, such as severe pain

FIG. 20-9 Typical appearance of tophi, which may occur in chronic gout, on an index finger.

or changes in urinary output. In some cases, urate kidney stones occur before the arthritis is present.

INTERVENTIONS

Gout is one of the easiest diseases for the health care provider to diagnose and treat in its early phases. If the patient receives treatment and adheres to drug therapy, he or she should experience no further symptoms and no change in body image or lifestyle. The patient with gout is treated on an ambulatory basis, but hospitalized patients may have a secondary diagnosis of the disease.

Drug Therapy

Drug therapy is the key to managing patients with gout. In acute gouty “attacks,” the inflammation subsides spontaneously within 3 to 5 days; however, most patients cannot tolerate the pain for that long. The drugs used for acute gout are different from those used for chronic gout. The health care provider typically prescribes a combination of colchicine (Colsalide) and an NSAID, such as indomethacin (Indocin, Novomethacin ) or ibuprofen (Motrin, Amersol ) for acute gout. IV colchicine works within 12 hours. The patient takes oral medications until the inflammation subsides, usually for 4 to 7 days.

For patients with repeated acute episodes or with chronic gout, the health care provider prescribes drugs to promote uric acid excretion or to reduce its production on a continuous, maintenance basis. Allopurinol (Zyloprim, Purinol ) or febuxostat (Uloric) is the drug of choice. As xanthine oxidase inhibitors, these drugs prevent the conversion of xanthine to uric acid. Teach patients to take them after meals and drink a glass of water with each dose to prevent GI distress.

Drinking at least 8 glasses of water each day helps prevent renal dysfunction. Remind patients that periodic follow-up laboratory tests, including liver enzymes, renal function studies, and complete blood count, are important because xanthine oxidase inhibitors cause liver dysfunction and bone marrow suppression.

Probenecid (Benemid, Benuryl ) can also be effective as a uricosuric drug in gout because it promotes the excretion of excess uric acid. Combination drugs that contain probenecid and colchicine (e.g., ColBENEMID) are also available. The health care provider and nurse monitor serum uric acid levels to determine the effectiveness of these medications. Aspirin should be avoided because it inactivates the effects of the drug.

For patients with severe gout who do not respond to other drugs (refractory gout), pegloticase (Krystexxa) can be prescribed as an IV dose every 2 weeks. This drug is an enzyme that works directly on uric acid and converts it to allantoin, which can be excreted by the kidneys. Monitor patients carefully for allergic reactions, including anaphylaxis, during and immediately after drug administration because pegloticase is a protein that is foreign to the body.

Nutrition Therapy

Whether or not to recommend special nutritional restrictions for patients with gout is controversial. Some physicians advocate a strict low-purine diet and advise patients to avoid foods such as organ meats, shellfish, and oily fish with bones (e.g., sardines). Some health care providers and dietitians believe that limiting protein foods, especially red and organ meats, is sufficient. Still others do not believe that diet restrictions affect treatment. It is well known, however, that excessive alcohol intake and fad “starvation” diets can cause a gouty attack. *Teach patients to determine which foods precipitate acute attacks and try to avoid them.*

In addition to food and beverage restrictions, patients with gout should avoid all forms of aspirin and diuretics because they may precipitate an attack. Likewise, excessive physical or emotional stress can exacerbate the disease. Surgery or acute illness, like a myocardial infarction, can also trigger an attack. Stress-management techniques may be helpful for the patient with gout.

Teach the patient to drink plenty of fluids to prevent the formation of urinary stones. Increasing fluid intake helps dilute urine and prevent sediment formation. Uric acid is more soluble in urine with a high pH and therefore is less likely to form urinary stones in that environment. The patient’s urinary pH can be increased with an intake of alkaline ash foods, such as citrus fruits and juices, milk, and certain other dairy products. The value of adhering to a strict diet rich in these foods is questionable, however.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

Which drug is not appropriate to treat the disease with which it is matched?

- A. Rheumatoid arthritis—allopurinol (Zyloprim)
- B. Osteoarthritis—celecoxib (Celebrex)
- C. Acute gout—colchicine (Colsalide)
- D. Systemic lupus erythematosus—prednisone (Deltasone)

OTHER CONNECTIVE TISSUE DISEASES

The care of patients with connective tissue diseases (CTDs) is often similar regardless of the specific diagnosis. This section describes other fairly common diseases that are classified as CTDs.

Polymyositis/Dermatomyositis

Polymyositis is a diffuse inflammatory disease of skeletal (striated) muscle that causes symmetric weakness and atrophy. When a rash accompanies polymyositis, the disease is called **dermatomyositis**. Both diseases vary in their mode of onset and progression and are characterized by spontaneous remissions and exacerbations. Women are affected twice as often as men, and men and women between 30 and 60 years of age are most susceptible to either disease.

In addition to proximal muscle and possible skin involvement, patients typically have polyarthritis, **polyarthralgia** (aching around multiple joints), and Raynaud's phenomenon (see Chapter 38). Patients with dermatomyositis have the characteristic heliotrope (lilac) rash and periorbital (around the eyes) edema. Malignant neoplasms are more common in these patients than in the rest of the population; some patients older than 55 years have malignancies. Most patients develop difficulty swallowing or talking because of severe muscle weakness.

These conditions are treated with high-dose steroids, immunosuppressive agents, and supportive care. Particular attention is given to nutrition because of swallowing problems.

Systemic Necrotizing Vasculitis

Necrotizing vasculitis is a term for a group of diseases whose primary manifestation is **arteritis** (inflammation of arterial walls), which causes ischemia in the tissues usually supplied by the involved vessels. The drug of choice for most types of vasculitis is chronic steroid therapy (prednisone), although immunosuppressive drugs may be used also.

Polyarteritis nodosa affects middle-aged men most often and involves every body system. Treatment is similar to that for systemic lupus, but the prognosis is not as promising. Renal disorders and cardiac involvement are the most common causes of death. *Hypersensitivity vasculitis* is the most common form of vasculitis and primarily causes skin lesions as an allergic response to drugs, infections, or tumors. *Takayasu's arteritis*, or the *aortic arch syndrome*, is also called the "pulseless" disease. Women in their 20s, particularly those of Japanese descent, are affected most often. Cerebral ischemia is manifested by visual changes, syncope, and vertigo.

Polymyalgia Rheumatica and Temporal Arteritis

Polymyalgia rheumatica (PMR) is a clinical syndrome characterized by stiffness, weakness, and aching of the proximal musculature (i.e., the shoulder and pelvic girdles). Systemic manifestations such as low-grade fever, arthralgias (aching around joints) and stiffness, fatigue, and weight loss occur in most cases. The most common joints affected are the neck, shoulder, and hip joints. Stiffness is worse in the morning.

Most patients have an increased erythrocyte sedimentation rate (ESR) and a normochromic, normocytic anemia

CHART 20-14 KEY FEATURES

Giant Cell (Temporal) Arteritis

Systemic Manifestations

- Fatigue, malaise
- Fever
- Weight loss
- Night sweats

Myalgic Manifestations (if patient has polymyalgia rheumatica [PMR])

- Proximal, symmetric muscle pain
- Stiffness

Arteritic Manifestations

- Erythema
- Pain (especially localized temporal headache)
- Swelling
- Tenderness (especially scalp)
- Amaurosis fugax (temporary vision loss in one eye)
- Diplopia or any vision change (requires urgent management)

(see Chart 20-8). The disease commonly occurs in women older than 50 years and typically responds to low-dose steroid therapy in several days.

Giant cell arteritis (GCA), or *temporal arteritis (TA)*, occurs in as many as 20% of people with PMR. GCA is a systemic vasculitis that affects large and midsize arteries. Clinical manifestations may be classified as systemic, myalgic, and arteritic (Chart 20-14).

The cause of both PMR and GCA is unknown, but a genetic predisposition related to HLA-DRB1 is likely. The disorder is easy to miss because most patients are older women who report declining vision (also an age-related change). GCA is treated *urgently* with high doses of corticosteroids, often as high as 40 to 80 mg daily. Taking calcium and vitamin D is important for preventing osteoporosis that can result from steroid therapy, especially in middle-aged women.

Ankylosing Spondylitis

Ankylosing spondylitis (AS) is also known as *Marie-Strümpell disease* or *rheumatoid spondylitis*. The disease affects the vertebral column and causes spinal deformities. Although this disorder is present in both men and women at any age in adulthood, white men younger than 40 years are most commonly affected. Other features include **iritis** (inflammation of the iris), arthritis or **arthralgia** (joint aching), and nonspecific systemic manifestations such as malaise and weight loss.

GENETIC/GENOMIC CONSIDERATIONS

Although the exact cause is unknown, ankylosing spondylitis is associated with the *HLA-B27* alleles. The risk for developing AS is 150 times greater for people with *HLA-B27* than for those without it. However, only a small percentage of people who have it actually develop the disease. One explanation is that there are many subtypes of *HLA-B27* that need further research for predicting who is most at risk for AS (Nussbaum et al., 2007).

Compromised respiratory function caused by a rigid chest wall is the major threat to health. Most patients function

normally but live with chronic discomfort. As in other types of inflammatory arthritis, anti-inflammatory drugs, heat applications, and physical therapy are the key components of management (see earlier discussion of pain management for rheumatoid arthritis, p. 337).

Disease-modifying antirheumatic drugs (DMARDs), such as methotrexate (Rheumatrex), have been successful in slowing AS progress. Biological response modifiers (BRMs) (TNF inhibitors), such as infliximab (Remicade), have also been approved for managing ankylosing spondylitis. Teach the patient taking these drugs to avoid crowds and people who have infections because BRMs increase the patient's susceptibility to infection (see [Chart 20-9](#)). Sulfasalazine (Azulfidine) may also be used to treat AS. Before beginning the drug, ask the patient if he or she is allergic to sulfa drugs.

Refer patients with AS and their families to the Spondylitis Association of America (www.spondylitis.org) for information and support. This organization also sponsors research for the management of AS.

Reiter's Syndrome

As with ankylosing spondylitis, Reiter's syndrome is associated with the HLA-B27 antigen. This disease usually affects young white men but can also affect women. The complete syndrome is a triad of arthritis, conjunctivitis, and **urethritis** (inflammation of the urethra) resulting from exposure to sexually transmitted disease, such as chlamydia, or intestinal infection, such as shigella or salmonella. Urethritis in men is often the first clinical manifestation. Although the disease is characterized by this triad of manifestations, other conditions such as **balanitis circinata** (ringlike inflammation of the glans penis) and skin lesions are equally significant for confirmation of the diagnosis.

Management is symptomatic and may be complex if there is organ involvement. Antibiotics such as minocycline (Minocin) and amoxicillin/clavulanate (Augmentin) are frequently used to manage the infection. NSAIDs, physical therapy, and other symptomatic treatment are used to manage the disease.

Marfan Syndrome

Marfan syndrome is an autosomal dominant connective tissue disease in which abnormalities of the skeletal, ocular, cardiopulmonary, and central nervous systems result from a basic defect in extracellular microfibrils. Microfibrils are very small fibers within cells.

GENETIC/GENOMIC CONSIDERATIONS

Marfan syndrome results from mutations in the fibrillin 1 gene (*FBN1*). This gene encodes fibrillin 1, which forms microfibrils in both elastic and nonelastic tissues (e.g., the skin, the outer layer of the aorta). Patients with Marfan syndrome have a 50% chance of having a child with the disease (Nussbaum et al., 2007). Genetic counseling should also be part of the interdisciplinary plan of care, especially for women of childbearing age.

Patients with the classic form of Marfan syndrome tend to be excessively *tall* and have *elongated hands and feet*. The diagnosis of milder forms of Marfan syndrome is often missed in young men, especially athletes involved in sports such as basketball.

Other skeletal abnormalities include *scoliosis*, a funnel-shaped chest, loss of the normal cervical curve, and hyperextensibility of the joints. Subluxation of the lens is usually bilateral and occurs by the age of 5 years, causing decreased visual acuity or glaucoma.

Cardiovascular problems are responsible for most deaths resulting from Marfan syndrome. The average life span is shortened, often with death in the 30s. Mitral valve prolapse with regurgitation and aortic aneurysm with regurgitation and rupture are common. The patient is closely monitored by echocardiography.

Management is both palliative and preventive and includes careful monitoring, cardiovascular medications, and orthopedic surgery if needed.

Infectious Arthritis

Any infectious agent can invade the joint space and cause inflammation and tissue destruction. Certain pathogens, such as *Staphylococcus aureus*, destroy tissue rapidly; others, especially viruses, do not cause irreversible damage. The cornerstone of management is local or systemic antibiotic therapy for 6 to 8 weeks.

Lyme Disease

Lyme disease is a reportable systemic infectious disease caused by the spirochete *Borrelia burgdorferi* and results from the bite of an infected deer tick, also known as the *black-legged tick*. It is the most common vector-borne disease in the United States and Europe. Most cases of the disease in the United States are seen in New England; the mid-Atlantic states, including Maryland and Virginia; the upper Midwest, including Wisconsin and Minnesota; and northern California, especially during the summer months.

In the early and *localized stage I*, the patient appears with *flu-like symptoms*, **erythema migrans** (round or oval, flat or slightly raised rash), and *pain and stiffness in the muscles and joints*. Most patients in the United States tend to have only one lesion, sometimes referred to as a "*bull's-eye lesion*." Symptoms begin within 3 to 30 days of the tick bite, but most present in 7 to 14 days. Antibiotic therapy, such as doxycycline or amoxicillin, is prescribed during this uncomplicated stage for 14 to 21 days. Erythromycin can be used for patients who are allergic to penicillin. Without treatment, these symptoms tend to disappear in about 4 to 5 weeks.

If not treated or if treatment is not successful, the patient progresses to the more serious complications of Lyme disease. *Stage II (early disseminated stage)* occurs 2 to 12 weeks after the tick bite. The patient may develop *carditis* with *dysrhythmias*, *dyspnea*, *dizziness*, or *palpitations*, as well as central nervous system disorders such as *meningitis*, *facial paralysis* (often misdiagnosed as Bell's palsy), and *peripheral neuritis*. For severe disease, IV antibiotics (e.g., ceftriaxone or cefotaxime) are given for at least 30 days.

If Lyme disease is not diagnosed and treated in the earlier stages, later chronic complications (e.g., *arthritis*, *chronic fatigue*, *memory/thinking problems*) can result. This *late stage III (chronic persistent stage)* occurs months to years after the tick bite. *For some patients, the first and only sign of Lyme disease is arthritis.* In some cases, the disease may not respond to antibiotics in any stage and the patient develops permanent damage to joints and the nervous system. *Prevention is the best strategy for Lyme disease.* Teach patients to follow the

measures outlined in [Chart 20-15](#) to prevent Lyme and other tick-borne diseases. Tell them about community resources such as the Lyme Disease Foundation (www.lyme.org) for more information.

Pseudogout

Pseudogout is a disease that mimics the clinical manifestations of gout. In this disease, however, the crystals deposited in the joints are calcium pyrophosphate, not sodium urate. These crystals usually migrate to cartilage, but they can also deposit in tendons, ligaments, and synovium.

The patient most susceptible to pseudogout is an older hospitalized male. Although the cause is not certain, the incidence is highest in men with metastatic cancer or endocrine imbalances such as hypothyroidism. NSAIDs usually control manifestations of the disease.

Psoriatic Arthritis

Psoriatic arthritis (PsA) affects about 30% of people who have psoriasis—a skin condition characterized by a scaly, itchy rash, usually on the elbows, knees, and scalp (National Psoriasis Foundation). Fingernail and toenail lifting and pitting may also occur (see [Chapter 27](#) for discussion of this disease). The joint pain associated with psoriasis is often associated with stiffness, especially in the morning. Neck and back pain are particularly common, but various forms of the disease can cause small joint arthritis or involvement of the sacroiliac joints of the spine.

PsA occurs most often in people between 30 and 50 years of age in men and women of all races. Nail symptoms are common in patients who have the associated arthritis. Causes may include genetic and environmental factors, infectious agents, and immune system dysfunction.

CHART 20-15 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Prevention and Early Detection of Lyme Disease

- Avoid heavily wooded areas or areas with thick underbrush, especially in the spring and summer months.
- Walk in the center of the trail.
- Avoid dark clothing. Lighter-colored clothing makes spotting ticks easier.
- Use an insect repellent (DEET) on your skin and clothes when in an area where ticks are likely to be found.
- Wear long-sleeved tops and long pants; tuck your shirt into your pants and your pants into your socks or boots.
- Wear closed shoes or boots and a hat or cap.
- Bathe immediately after being in an infested area, and inspect your body for ticks (about the size of a pinhead); pay special attention to your arms, legs, and scalp.
- Check your pets for ticks.
- Gently remove with tweezers or fingers covered with tissue or gloves any tick that you find (do not squeeze). Dispose of the tick by flushing it down the toilet (burning a tick could spread infection).
- After removal, clean the tick area with an antiseptic such as rubbing alcohol.
- Wait 4 to 6 weeks after being bitten by a tick before being tested for Lyme disease (testing before this time is not reliable).
- Report symptoms, such as a rash or influenza-like illness, to your physician immediately.

Most patients do not experience destructive and deforming arthritis affecting more than three joints, but those who do have a major impact on their quality of life. Treatment is focused on managing joint pain and inflammation, controlling skin lesions, and slowing the progression of the disease. Health teaching for skin care is similar to that for lupus. Management of joint inflammation is similar to that for rheumatoid arthritis. Methotrexate (Rheumatrex), sulfasalazine (Azulfidine), and biological response modifiers, such as etanercept (Enbrel) and golimumab (Simponi), have been used with success.

Several newer types of drugs have also been approved for psoriatic arthritis. Ustekinumab (Stelara) targets the cytokines interleukin (IL)-12 and IL-23 to decrease inflammation. Alefacept (Amevive) is an IV immunosuppressive drug (T-cell blocker) that is reserved for moderate to severe disease. Teach patients taking these drugs that they are prone to infection. Remind them to avoid crowds and anyone with an infection.

Acitretin (Soriatane) is an oral retinoid given for patients with severe disease. Teach patients to take the drug once a day with a meal and follow up with laboratory testing for liver enzymes.

The National Psoriasis Foundation (www.psoriasis.org) is an excellent community resource for patients and their families. Further discussion regarding management of psoriasis can be found in [Chapter 27](#).

Other Disease-Associated Arthritis

A number of other diseases can cause secondary arthritis. Tuberculosis, Crohn's disease, ulcerative colitis, hemophilia, and sickle cell anemia are typical examples. To manage joint involvement, the primary disease is treated. For example, when a patient with Crohn's disease is in remission, joint manifestations also subside. Conditions in which joint involvement can occur are presented in [Table 20-3](#).

Fibromyalgia Syndrome

Fibromyalgia syndrome (FMS), also referred to as simply *fibromyalgia*, is a chronic pain syndrome, not an inflammatory disease. However, arthritis and other comorbidities are commonly present in patients diagnosed with FMS. Pain, stiffness, and tenderness are located at specific sites in the back of the neck, upper chest, trunk, low back, and extremities. These tender points are also known as **trigger points** and can typically be palpated to elicit pain in a predictable, reproducible pattern. The pain is typically described as burning and gnawing. Increased muscle tenderness may be caused by the inability to tolerate pain, possibly related to dysfunction in the brain, especially the thalamus and hypothalamus (McCance et al., 2010).

TABLE 20-3 COMMON DISORDERS ASSOCIATED WITH ARTHRITIS

• Crohn's disease	• Hyperparathyroidism
• Ulcerative colitis	• Hyperthyroidism
• Tuberculosis	• Diabetes mellitus
• Hemophilia	• Sickle cell anemia crisis
• Whipple's disease	• Psoriasis
• Intestinal bypass surgery	• Infection

The pain and tenderness tend to come and go but typically worsen in response to stress, increased activity, and weather conditions. The patient reports mild to severe fatigue, and sleep disturbances are common. Some people report numbness or tingling in their extremities, and others are sensitive to noxious odors, loud noises, and bright lights. Headaches and jaw pain are also common. Secondary FMS can accompany any connective tissue disease (CTD), particularly lupus and rheumatoid disease, and may not necessarily be related to sleep patterns.

Other symptoms include:

- Gastrointestinal (GI), including abdominal pain, diarrhea and constipation, and heartburn
- Genitourinary, including dysuria, urinary frequency, urgency, and pelvic pain
- Cardiovascular, including dyspnea, chest pain, and dysrhythmias
- Visual, including blurred vision and dry eyes
- Neurologic, including forgetfulness and concentration problems

Many with these symptoms become frustrated because they are not properly diagnosed and are in constant pain and discomfort.

Some patients are diagnosed as having chronic fatigue syndrome (CFS). CFS, migraine headache, irritable bowel syndrome (IBS), and myofascial pain are often present in those with FMS. As a result, patients can become depressed and anxious.

Most patients are women between 30 and 50 years of age. It is unlikely that the disease is caused by one factor. Possible precipitating factors include CFS, Lyme disease, trauma, and flu-like illness (McCance et al., 2010). FMS may also be aggravated by deep-sleep deprivation. Teach patients to limit caffeine, alcohol, or other unnecessary substances that could interfere with deep sleep. Establish a regular sleep pattern.

Pregabalin (Lyrica) and duloxetine HCl (Cymbalta), antidepressant drugs, are approved for fibromyalgia nerve pain. These drugs work to increase the release of serotonin and norepinephrine, neurotransmitters in the brain. Teach the patient that these drugs can cause drowsiness and sleepiness and that alcohol should be avoided while taking them.

Tricyclic antidepressive agents, such as amitriptyline (Elavil, Apo-Amitriptyline ♣) or nortriptyline (Pamelor), may promote sleep and reduce pain or muscle spasm. These drugs should be used with caution in older adults because they can cause confusion and orthostatic hypotension. Trazodone (Desyrel) may be preferred for this population because of its minimal side effects. Tramadol (Ultram) is also effective for managing fibromyalgia. This drug has tricyclic effects and opioid properties to help relieve pain.

Physical therapy along with NSAIDs and possibly muscle relaxants may also be prescribed to help decrease fibromyalgia pain. Instruct the patient to exercise regularly. Home exercise should include stretching, strengthening, and low-impact aerobic exercise. Walking, swimming, rowing, biking, and water exercise are good examples of low-impact exercise.

Complementary and alternative therapies, such as tai chi, acupuncture, hypnosis, and stress management, may help some patients with symptom relief. Refer patients to the land, water, and walking exercise pamphlets produced by the Arthritis Foundation (www.arthritis.org). Inform them about the National Fibromyalgia Association for additional information and patient and family support (www.fmaware.org).

Chronic Fatigue Syndrome

Chronic fatigue syndrome (CFS), also known as *chronic fatigue and immune dysfunction syndrome (CFIDS)*, is a chronic illness in which patients have severe fatigue for 6 months or longer, usually following flu-like symptoms. In addition, four or more of these criteria must be met for a diagnosis of CFS:

- Sore throat
- Substantial impairment in short-term memory or concentration
- Tender lymph nodes
- Muscle pain
- Multiple joint pain with redness or swelling
- Headaches of a new type, pattern, or severity (not familiar to the patient)
- Unrefreshing sleep
- Postexertional malaise lasting more than 24 hours

Chronic fatigue syndrome is most common in women and is not limited to any socioeconomic group or age. There is no laboratory test to confirm the diagnosis, and therefore many people with the disease probably have not been diagnosed. The cause is unknown, although immune, endocrine, neurologic, and environmental factors are being studied.

Management of the patient is challenging in that there is no cure for CFS. Treatment is supportive and focuses on alleviation or reduction of symptoms. For example, NSAIDs may help with body aches and pain. Low-dose antidepressants may also be effective in promoting sleep and preventing or treating depression. Teach the patient to follow healthy practices, such as adequate sleep, proper nutrition, regular exercise (but not excessive to increase fatigue), stress management, and energy conservation. Complementary and alternative therapies, such as acupuncture, tai chi, massage, and herbal supplements, may be helpful for some patients.

Refer the patient to the National Chronic Fatigue Syndrome and Fibromyalgia Association for information and support groups (www.ncfsa.org).

Mixed Connective Tissue Disease

A diagnosis of mixed CTD is made when a patient presents with clinical manifestations that are not typical of any one CTD. About 10% of patients with CTDs are classified as having mixed disease. Some of these are overlap syndromes, in which two or more diseases occur at the same time. Common examples are (1) systemic lupus erythematosus (SLE) plus systemic sclerosis (SSc) and (2) rheumatoid arthritis (RA) plus SLE. Management depends on the clinical manifestations, but often the patient is treated as having SLE.

NURSING CONCEPT REVIEW

What might you NOTICE if the patient has impaired protection as a result of arthritis or other connective tissue disease (CTD)?

- Joint inflammation (redness, swelling, pain)
- Impaired joint mobility and stiffness
- Joint deformity
- Difficulty ambulating
- Fever
- Rash
- Report of weight loss and fatigue
- Other manifestations that indicate organ involvement, such as dysrhythmias (heart) and decreased urinary output (kidneys)

What should you INTERPRET and how should you RESPOND to a patient with impaired protection as a result of arthritis or other CTD?

Perform and interpret focused physical assessment findings, including:

- Joint assessment, including range of motion
- ADL ability
- Pain intensity and quality
- Body weight
- Ability to cope with disease
- Vital signs
- Other assessments related to specific organ involvement (e.g., cardiac assessment)

Respond:

- Provide pain control interventions, including drug therapy and nonpharmacologic measures (e.g., music, diversional therapy).

- Collaborate with members of the health care team to improve mobility and ambulation, if needed.
- Teach about drug therapy, including the expected and adverse effects.
- Teach about nonpharmacologic measures to control pain, including ice and heat, and CAM therapies, such as glucosamine.
- Report manifestations of organ involvement to the health care provider for possible immediate intervention (e.g., drug therapy for severe dysrhythmias).
- Monitor laboratory test results to determine progress of treatment.
- Continue to assess for changes in the patient's condition, including new or additional manifestations of organ involvement.
- Encourage patients and their families to discuss their feelings about chronic illness and possible body image changes.
- Help identify coping strategies, and provide information about community and professional resources and support groups.

On what should you REFLECT?

- Monitor the patient's response to pain control interventions.
- Evaluate the patient's and family's knowledge of the disease and its management.
- Evaluate the patient's and family's stress levels and coping strategies.
- Think about what else you might do to promote mobility.
- Decide whether you need to provide alternative interventions or additional health teaching.

GET READY FOR THE NCLEX® EXAMINATION!

KEY POINTS

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Collaborate with the health care team to manage chronic pain and increase mobility for patients with arthritis and other CTDs.
- Prioritize care for patients with systemic lupus erythematosus (SLE) and systemic sclerosis (SSc) by monitoring for life-threatening complications, such as renal failure.

Health Promotion and Maintenance

- Provide information about community resources for patients, especially professional organizations such as the Arthritis Foundation and Lupus Foundation.
- Reinforce the importance of good health practices, such as adequate sleep, proper nutrition, regular exercise, and

stress-management techniques for patients with arthritis and other CTDs.

- Teach patients with arthritis what exercises to do ([Chart 20-5](#)), joint protection techniques ([Chart 20-6](#)), and energy conservation guidelines ([Chart 20-10](#)).
- Teach patients with SLE to avoid sunlight; exacerbations of the disease may be triggered.
- Remind patients with gout to avoid factors that trigger an attack, such as aspirin, organ meats, and alcohol.
- Teach people ways to prevent or detect early Lyme disease as listed in [Chart 20-15](#).

Psychosocial Integrity

- Recognize that patients with rheumatoid arthritis (RA) may have body image disturbance as a result of potentially deforming joint involvement and nodules.

GET READY FOR THE NCLEX® EXAMINATION! —cont'd

- Encourage patients with arthritis and connective tissue diseases to discuss their chronic illness and identify coping strategies that have previously been successful.
- Be aware that chronic, painful diseases affect the patient's quality of life and role performance.
- Recognize that patients with fibromyalgia syndrome (FMS) and chronic fatigue syndrome (CFS) are often frustrated because they have not been diagnosed or have been misdiagnosed.
- Teach patients with FMS and CFS that antidepressant drugs can promote sleep and decrease pain, as well as prevent or treat the depression that is common with these illnesses.
- Remind patients to avoid crowds and other possible sources of infection when they are taking immunosuppressant drugs.
- Implement interventions for patients having total joint arthroplasty (TJA) to prevent venous thromboembolic complications (e.g., anticoagulants, exercises, sequential compression devices); observe the patient for bleeding when he or she is taking anticoagulants.
- Be careful when positioning a patient after a total hip arthroplasty (THA) to prevent dislocation; do not hyperflex the hips or adduct the legs (see [Chart 20-3](#)).
- Teach patients receiving biological response modifiers (BRMs) and other disease-modifying agents to avoid crowds and people with infections.

Physiological Integrity

- Be aware that most of the connective tissue diseases and arthritic disorders have a genetic basis as part of their etiology; most are also classified as autoimmune diseases and have remissions and exacerbations.
- Differentiate OA as primarily a degenerative joint problem and RA as a systemic disease.
- Realize that older patients have OA more than younger patients; younger patients have RA more than older adults; other differences between the two diseases are summarized in [Table 20-1](#).
- Teach patients who have osteoarthritis (OA) or are prone to the disease to lose weight (if obese), avoid trauma, and limit strenuous weight-bearing activities.
- Instruct patients with arthritic pain to use multiple modalities for pain relief, including ice/heat, rest, positioning, complementary and alternative therapies, and medications as prescribed.
- Teach patients to monitor and report side and adverse effects of drugs used to treat OA and connective tissue diseases.
- Teach patients who are taking hydroxychloroquine (Plaquenil) to have frequent (every 6 months) eye examinations to monitor for retinal changes.
- Monitor and interpret laboratory test results for patients with autoimmune connective tissue diseases as highlighted in [Chart 20-8](#).
- Assess for therapeutic and adverse effects of drugs used for arthritis and connective tissue diseases as specified in [Chart 20-9](#).
- Be aware that disease-modifying antirheumatic drugs (DMARDs) and BRMs slow the progression of connective tissue diseases, especially RA and SLE.
- Assess patients with rheumatoid arthritis for early or late clinical manifestations as listed in [Chart 20-7](#).
- Differentiate clinical manifestations and prognosis for patients with systemic lupus erythematosus (SLE) versus systemic sclerosis (SSc) as listed in [Chart 20-11](#).
- Prioritize care by assessing for swallowing ability in patients who have SSc; collaborate with the dietitian for food modifications if needed.
- Monitor for acute joint inflammation in patients with a history of gout; the great toe and other small joints are most typically affected.
- Assess for visual symptoms (indicating possible giant cell arteritis) in patients with polymyalgia rheumatica; report changes immediately to the health care provider.
- Be aware that arthritis often accompanies other diseases, such as psoriasis, Crohn's disease, and hemophilia.

Care of Patients with HIV Disease and Other Immune Deficiencies

James G. Sampson and M. Linda Workman

<http://evolve.elsevier.com/Iggy/>

Answer Key for NCLEX Examination Challenges and
Decision-Making Challenges
Audio Glossary

Concept Map Creator
Key Points
Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Use appropriate techniques to reduce the risk for infection in an immunosuppressed patient.
2. Use Standard Precautions to prevent human immune deficiency virus (HIV) transmission to you, patients, and other members of the health care team.
3. Ensure that confidentiality of HIV status is maintained by all health care team members.

Health Promotion and Maintenance

4. Teach all sexually active people to use safer sex practices.
5. Assess all patients for high-risk behaviors for HIV disease.

Psychosocial Integrity

6. Teach family members reorientation techniques to use when the patient is confused.
7. Respect the patient's right to inform or not to inform family members about his or her HIV status.

8. Use a nonjudgmental approach when discussing sexual practices, sexual behaviors, and recreational drug use.

Physiological Integrity

9. Compare primary and secondary immune deficiencies for cause and onset of problems.
10. Explain the differences in nursing care required for a patient with a pathogenic infection versus a patient with an opportunistic infection.
11. Distinguish between the conditions of HIV infection and acquired immune deficiency syndrome (AIDS) for clinical manifestations and risks for complications.
12. Describe the ways in which HIV is transmitted.
13. Coordinate nursing care for the patient with AIDS who has impaired gas exchange.
14. Identify teaching priorities for the HIV-positive patient receiving highly active antiretroviral therapy.

Immune system function is concerned with helping the body stay healthy by preventing the growth of infectious organisms and abnormal cells, such as cancer cells. It assists the body to monitor and maintain those cells and substances that are considered “self,” belonging to the body. For example, newly made cells and compatible blood transfusions are deemed self and safe by the immune system. However, when the immune system detects the presence of a protein or cell that does not belong to the body and represents a potential threat, its job is then to attack and destroy the “non-self” or “foreign”

substance. Infection is a major threat. We are exposed to many organisms every day. The efficiency of the immune system prevents disease despite this exposure.

When the immune system fails to recognize infectious agents, severe local and systemic infections are not suppressed or controlled. Immune system failure can be the result of a primary (congenital) immune deficiency in which one or more parts of the system are not functioning properly from birth. These problems are usually genetic mutations that are discovered in the infant or child who is repeatedly sick.

FIG. 21-1 The human immune deficiency virus (HIV).

Immune system failure can also be secondary (acquired after birth) as the result of viral infection, contact with a toxin, or medical therapy. These problems can cause a normal immune system to stop functioning or to function less efficiently. In either case, the immune system can no longer distinguish what should be in the body from a foreign invader. The consequences for the immune-deficient patient can range from mild, localized health problems to total immune system failure, leaving the body open to attack from any foreign pathogen.

ACQUIRED (SECONDARY) IMMUNE DEFICIENCIES

HIV INFECTION AND AIDS

Pathophysiology

Human immune deficiency virus (HIV) infection can progress to acquired immune deficiency syndrome (AIDS), which is the most common secondary immune deficiency disease in the world (World Health Organization [WHO], 2010). First identified in 1981, HIV/AIDS is now a serious worldwide epidemic.

Etiology and Genetic Risk

The cause of HIV infection is a virus—the human immune deficiency virus. Like most viruses, HIV is a parasite looking for a way into a cell, to take over the cell, and to force the cell into making more copies of the virus. These new virus particles then look for additional cells to infect, repeating the cycle as long as there are new host cells to infect.

The HIV Infectious Process. Viral particle features include an outer envelope with special “docking proteins,” known as *gp41* and *gp120*, that assist in finding a host (Fig. 21-1). Inside, the virus has two protein coatings and the genetic material along with the enzymes *reverse transcriptase* (RT) and *integrase*. The first challenge is for the HIV particle to get inside a host cell. HIV accomplishes this task by first finding

FIG. 21-2 The CD4+ T-lymphocyte receptors for the HIV “docking” proteins.

a way into the host’s bloodstream. Once in the blood, HIV “hijacks” certain cells. One of the cells that it hijacks is the *CD4 T-cell*, also known as the *CD4 cell*, *helper/inducer T-cell*, or *T4-cell* (Kaufman, 2011) (see Chapter 19). This cell directs immune system defenses and regulates the activity of all immune system cells. If HIV successfully enters a CD4 T-cell, it can then create more virus particles.

Virus-host interactions are needed for disease development. When a person is infected with HIV, the virus randomly “bumps” into many cells. The docking proteins on the outside of the virus try to find special receptors on a host cell that will allow the virus to bind and then enter the cell. The CD4+ T-cell has receptors on its surface known as *CD4*, *CCR5*, and *CXCR4* (Fig. 21-2). Proteins on the HIV particle surface, known as *gp120* and *gp41*, recognize these receptors on the CD4+ T-cell. For the virus to enter this cell, *both* the *gp120* and the *gp41* must bind to the receptors. The *gp120* first binds to the primary CD4 receptor, which changes its shape and allows the *gp41* to bind to one of the co-receptors (either the *CCR5* receptor or the *CXCR4* receptor). This attachment allows the virus to then enter the CD4+ T-cell (Fig. 21-3). *Viral binding to the CD4 receptor and to either of the co-receptors is needed to enter the cell.* (The new drug class

known as *entry inhibitors* works here to block the receptor and prevent the interaction needed for entry of HIV into the CD4+ T-cell.)

Viruses, like human cells, have genetic material. After entering a host cell, HIV must get its genetic material into the host cell's DNA. HIV belongs to a family of viruses called **retroviruses**. The genetic material of the human cell is double-stranded DNA (ds-DNA). The genetic material of HIV is single-stranded ribonucleic acid (RNA) (ss-RNA). To infect and take over a human cell, the genetic material must be the same. HIV overcomes this problem by bringing along an enzyme at the time of infection, *reverse transcriptase* (RT). RT takes HIV's ss-RNA and converts it into ds-DNA, which makes the viral genetic material the same as human DNA. (The drug classes known as *nucleoside analog reverse transcriptase inhibitors* [NRTIs] and *non-nucleoside reverse transcriptase inhibitors* [NNRTIs] work here to inhibit HIV reverse transcriptase.) Then HIV must get its DNA into the nucleus of the CD4+ T-cell and place it within the human DNA. HIV also brings an enzyme called *integrase*. This

enzyme allows the viral ds-DNA to be inserted into the host ds-DNA, which completes the infection of the CD4+ T-cell. (The drug class known as *integrase inhibitors* works here to prevent viral DNA from integrating into the cell's normal human DNA.)

HIV particles are made within the infected CD4+ T-cell, using all the metabolic machinery of the host. The new virus particle is made in the form of one long protein strand. The strand is clipped, using chemical enzyme scissors called *HIV protease*, into several small functional pieces. These pieces are formed into a new finished viral particle. (The drug class known as *protease inhibitors* works here to inhibit HIV protease.) Once the new virus particle is finished, it fuses with the infected cell's membrane and then buds off in search of another CD4+ T-cell to infect (Fig. 21-4).

Effects of HIV infection are related to the new genetic instructions that now direct CD4+ T-cells to change their role in immune system defenses. The new role is to be an "HIV factory." The immune system is made weaker by removing some CD4+ T-cells from circulation, and the most important cell in the immune system becomes an HIV factory. Up to 10 billion virus particles are made daily. In early HIV infection, the immune system can still attack and destroy most of the newly created virus particles. With time, however, the number of HIV particles overwhelms the immune system. Gradually, CD4+ T-cell counts fall, viral numbers (*viral load*) rise, and without treatment, the patient eventually dies of opportunistic infections or cancer.

Everyone who has AIDS has HIV infection; however, not everyone who has HIV infection has AIDS. The distinction rests with the number of CD4+ T-cells the patient has and whether any opportunistic infections have occurred. A healthy adult usually has at least 800 to 1000 of these cells per cubic millimeter (mm³) of blood. The number of CD4+ T-cells is reduced in the person with HIV disease.

FIG. 21-3 The successful interaction of the HIV "docking" proteins with the CD4+ T-lymphocyte receptors.

FIG. 21-4 The life cycle of the HIV and sites of action for anti-HIV therapy.

About 50% to 90% of people who are first infected with HIV develop an acute infection within 4 weeks. Manifestations of this acute HIV infection can be fever, night sweats, chills, headache, and muscle aches. All of these problems can be caused by exposure to almost any virus (e.g., influenza)—not just to HIV. Many people with this acute HIV infection also have a rash and a sore throat, which is often confused with mononucleosis and viral meningitis. With time, these symptoms cease and the person feels well again. Actually, a “war is going on” in the body between HIV and the immune system.

As time passes, with more CD4+ T-cells infected and taken out of service, this cell count drops to below normal levels and those that remain may not function normally. Poor CD4+ T-cell function as a result of HIV infection leads to these immune system abnormalities:

- Lymphocytopenia (decreased numbers of lymphocytes)
- Increased production of incomplete and nonfunctional antibodies
- Abnormally functioning macrophages

As the CD4+ T-cell level drops, the patient is at risk for bacterial, fungal, and viral infections, as well as opportunistic cancers. **Opportunistic infections** are those caused by organisms that are present as part of the body’s normal environment and are kept in check by normal immune function. They occur because of the profound immunosuppression in the person with AIDS. These infections may result from a newly acquired infection or reactivation of an old infection.

A diagnosis of AIDS requires that the person be HIV positive and have either a CD4+ T-cell count of less than 200 cells/mm³ or an opportunistic infection. Once AIDS is diagnosed, even if the patient’s cell count goes higher than 200 cells/mm³ or the infection is successfully treated, the AIDS diagnosis remains and the patient never reverts to being just HIV positive.

HIV Classification. The Centers for Disease Control and Prevention (CDC), in a 1993 definition, classified HIV infection by correlating clinical conditions with three ranges of CD4+ T-cell counts. This classification was replaced in 2008 by defining four stages of the disease. In this new definition, laboratory confirmation of HIV infection (by enzyme-linked immunosorbent assay [ELISA] and Western blot analysis) plus CD4+ T-lymphocyte count or percentage and the presence or absence of the 26 AIDS-defining conditions (Table 21-1) determine the classification (CDC, 2008). *The person with HIV infection can transmit the virus to others at all stages of disease, but the recently infected person with a high viral load and those at end stage without drug therapy can be particularly infectious.*

- **Stage 1 CDC Case Definition** describes any patient with confirmed HIV infection and a CD4+ T-cell count of greater than 500 cells/mm³ or a CD4+ T-cell percentage of 29% or greater. A person at this stage has no AIDS-defining illnesses.
- **Stage 2 CDC Case Definition** describes any patient with a confirmed HIV infection and a CD4+ T-cell count between 200 and 499 cells/mm³ or a CD4+ T-cell percentage between 14% and 28%. A person at this stage has no AIDS-defining illnesses.
- **Stage 3 CDC Case Definition** describes any patient with a confirmed HIV infection and a CD4+ T-cell count of less than 200 cells/mm³ or a CD4+ T-cell percentage of less than 14%. A person who has higher CD4+ T-cell

counts or percentages but who also has a documented AIDS-defining illness meets the requirements of Stage 3 CDC Case Definition.

- **Stage 4 CDC Case Definition** is used to describe any patient with a confirmed HIV infection, but no information regarding CD4+ T-cell counts, CD4+ T-cell percentages, and AIDS-defining illnesses is available.

GENETIC/GENOMIC CONSIDERATIONS

About 1% of people with HIV infection are **long-term nonprogressors (LTNPs)**, sometimes called “elite controllers.” These people have been infected with HIV (as measured by ELISA) for at least 10 years and have remained asymptomatic, with CD4+ T-cell counts within the normal range and a viral load that is either undetectable or very low.

A genetic difference for this population is that their *CCR5/CXCR4* co-receptors on the CD4+ T-cells are abnormal and nonfunctional. Most LTNPs have mutations in both pairs of the co-receptors’ gene alleles. The mutation creates a defective receptor called *delta32*. This defective receptor does not bind to the HIV docking proteins. Cells with this defective receptor successfully resist the entrance of HIV. People who have only one mutated co-receptor gene allele have fewer normal co-receptors. Although these people can be infected with HIV, disease progression is slow compared with that in people who have normal co-receptor gene alleles.

TABLE 21-1 CENTERS FOR DISEASE CONTROL AND PREVENTION CLASSIFICATION OF AIDS-DEFINING CONDITIONS IN ADULTS

- Candidiasis of bronchi, trachea, or lungs
- Candidiasis of esophagus
- Cervical cancer, invasive
- Coccidioidomycosis, disseminated or extrapulmonary
- Cryptococcosis, extrapulmonary
- Cryptosporidiosis, chronic intestinal (>1 month’s duration)
- Cytomegalovirus disease (other than liver, spleen, or nodes)
- Cytomegalovirus retinitis (with loss of vision)
- Encephalopathy, HIV related
- Herpes simplex: chronic ulcers (>1 month’s duration) or bronchitis, pneumonitis, or esophagitis
- Histoplasmosis, disseminated or extrapulmonary
- Isosporiasis, chronic intestinal (>1 month’s duration)
- Kaposi sarcoma
- Lymphoid interstitial pneumonia or pulmonary lymphoid hyperplasia complex
- Lymphoma, Burkitt (or equivalent term)
- Lymphoma, immunoblastic (or equivalent term)
- Lymphoma, primary, of brain
- *Mycobacterium avium* complex or *Mycobacterium kansasii*, disseminated or extrapulmonary
- *Mycobacterium tuberculosis* of any site, pulmonary, disseminated, or extrapulmonary
- *Mycobacterium*, other species or unidentified species, disseminated or extrapulmonary
- *Pneumocystis jirovecii* pneumonia
- Pneumonia, recurrent (two instances within 12 months)
- Progressive multifocal leukoencephalopathy
- *Salmonella* septicemia, recurrent
- Toxoplasmosis of brain
- Wasting syndrome attributed to HIV

Centers for Disease Control and Prevention. (2008). Recommendations and reports: Appendix A—AIDS-defining conditions. *Morbidity and Mortality Weekly Report*, 57(RR-10), 9.

HIV Progression. The time from the beginning of HIV infection to development of AIDS ranges from months to years. The range depends on how HIV was acquired, personal factors, and interventions. For people who have been transfused with HIV-contaminated blood, for example, AIDS often develops quickly. For those who become HIV positive as a result of a single sexual encounter, the period is much longer before progression to AIDS. Other personal factors that may influence progression to AIDS include frequency of re-exposure to HIV, presence of other sexually transmitted diseases (STDs), nutritional status, and stress.

Incidence/Prevalence

Since the beginning of the epidemic in the United States, more than 1.2 million cases of HIV/AIDS have been diagnosed, and more than 617,025 people have died of AIDS. Currently, more than 600,000 people in the United States are living with HIV/AIDS (CDC, 2011). This number is less than the total number of people in the United States estimated to be infected with HIV (1.1 million to 1.8 million). Worldwide, about 40 to 60 million people are currently infected with HIV, at least 30 million deaths from AIDS have occurred, and 33 million people are living with AIDS (WHO, 2010).

AIDS hits hardest among people between 21 and 44 years of age. The loss of productivity and wage-earning power among this group devastates the patient and strains the insurance and health care industry.

Most AIDS cases in North America occur among men who have had sex with other men (MSM) (53%) or individuals of either gender who have used injection drugs (16%) (CDC, 2011). *The changing demographics of the infection indicate that the perception that HIV/AIDS is only a problem for homosexual white men is false* (Kirtan, 2011).

CULTURAL AWARENESS

Most new HIV infections reported in the United States occur in racial and ethnic minority groups, particularly among Blacks/African Americans and Hispanics (CDC, 2011) (Fig. 21-5). These two groups show an increasing trend in HIV infection compared with a leveling off among white people. Factors that may increase the incidence of HIV infection and progression to AIDS among minority groups include:

- Fear of or lack of faith in the U.S. health care system
- Poverty and limited access to high-cost drugs
- Homophobia leading to increased bisexual activity among men of color
- Health beliefs about HIV treatment

FIG. 21-5 Estimates of annual new HIV infections in the United States by ethnicity and race.

CONSIDERATIONS FOR OLDER ADULTS

Infection with HIV can occur at any age. Assess the older patient for risk behaviors, including a sexual and drug use history (Tangredi et al., 2008). Age-related decline in immune function increases the likelihood that the older adult will develop the infection after an HIV exposure. In the older woman, thinning of vaginal tissue as a result of decreased estrogen may increase susceptibility to all sexually transmitted diseases, including HIV infection. Cognitive deficits appear to occur earlier in the older adult with HIV (Vance, 2010).

WOMEN'S HEALTH CONSIDERATIONS

Women are the fastest growing group with HIV infection and AIDS. In North America, about 16% of people with HIV infection are women. Twenty-five percent of newly diagnosed cases are women. In less affluent countries, 50% of cases occur in women (WHO, 2010). Risk factors are sexual exposure (75%) and injection drug use (25%). Strategies specifically targeted to reducing sexual exposures of HIV to women may help prevent an increase in HIV infection in that group. Women with HIV infection have a poorer outcome with shorter mean survival time than that of men. This outcome may be the result of late diagnosis and social or economic factors that reduce access to medical care.

Gynecologic problems, especially persistent or recurrent vaginal candidiasis, may be the first signs of HIV infection in women. Other common problems include genital herpes, pelvic inflammatory disease, other sexually transmitted diseases (STDs), and cervical dysplasia or cancer.

Most women with HIV are of childbearing age. The effect of HIV on pregnancy outcomes includes higher incidence of premature delivery, low-birth-weight infants, and transmission of the disease to the infant. Appropriate antiretroviral drug therapy during pregnancy reduces the risk for transmitting the infection to the infant. (See the discussion on p. 363 in the Perinatal Transmission section.)

AIDS is a disease with a high mortality rate. The fatality rate is at least 60% for adults and, to date, there is no cure (WHO, 2010). Thus a major focus for health care in North America and worldwide is prevention of HIV infection. For those infected with HIV, drug therapy slows disease progression and, to be effective, it must be taken as prescribed for the rest of the patient's life.

Health Promotion and Maintenance

HIV has been found in most body fluids of infected patients, including blood, semen, vaginal secretions, breast milk, amniotic fluid, urine, feces, saliva, tears, cerebrospinal fluid, lymph nodes, cervical cells, corneal tissue, and brain tissue. The fluids with the highest concentrations of HIV are the semen and the blood. It is also present in vaginal fluids and breast milk. Thus HIV is transmitted most often in these three ways:

- Sexual: genital, anal, or oral sexual contact with exposure of mucous membranes to infected semen or vaginal secretions
- Parenteral: sharing of needles or equipment contaminated with infected blood or receiving contaminated blood products
- Perinatal: from the placenta, from contact with maternal blood and body fluids during birth, or from breast milk from an infected mother to child

Teach everyone about the transmission routes and ways to reduce their exposure (discussed next). Also stress that HIV is not transmitted by casual contact in the home, school, or

workplace. Sharing household utensils, towels and linens, and toilet facilities does not transmit HIV. In addition, HIV is not spread by mosquitoes or other insects.

! NURSING SAFETY PRIORITY

Action Alert

Teach all people, regardless of age, gender, ethnicity, or sexual orientation, that they are susceptible to HIV infection.

Sexual Transmission

The CDC describes the ABC safer sex methods as **A**, abstinence; **B**, be faithful; and **C**, condoms (CDC, 2009b). *Abstinence and mutually monogamous sex with a noninfected partner are the only absolutely safe methods of preventing HIV infection from sexual contact.* Many forms of sexual expression can spread HIV infection if one partner is infected. *The risk for becoming infected from a partner who is HIV positive is always present*, although some sexual practices are more risky than others. The virus concentrates most heavily in blood and seminal fluid, although it is also present in vaginal secretions. Thus risk differs by gender, sexual act, and the viral load of the infected partner.

Gender affects HIV transmission. HIV is most easily transmitted when infected body fluids come into contact with mucous membranes or nonintact skin. The vagina has much more mucous membrane than does the penis. Thus HIV, like all other sexually transmitted diseases (STDs), is more easily transmitted from infected male to uninfected female than vice versa. Teach women the importance of always either using a vaginal or dental dam or female condom, or having their male partners use a condom.

Sexual acts or practices that permit infected seminal fluid to come into contact with mucous membranes or nonintact skin are the most risky for sexual transmission of HIV. The practice with the highest risk is anal intercourse. In anal intercourse, the risk increases when the penis and seminal fluid of an infected person come into contact with the mucous membranes of the uninfected partner's rectum. *Anal intercourse in which the semen depositor (inserting or active partner) is infected is a very risky sexual practice regardless of whether the semen receiver (receiving partner) is male or female.* Anal intercourse not only allows seminal fluid to make contact with the mucous membranes of the rectum but also tears the mucous membranes, making infection more likely. Teach patients who engage in anal intercourse that the safer sex practice is for the semen depositor to wear a condom during this act.

Viral load, or the amount of virus present in blood and other body fluids, affects transmission. The higher the blood level of HIV (viremia), the greater the risk for sexual and perinatal transmission. Current highly active antiretroviral therapy (HAART) has caused the viral load of some infected patients to drop below detectable levels. *Although there is less virus in seminal or vaginal fluids of people receiving HAART, the risk for transmission still exists* (Kirtan, 2011).

Safer sex practices are those that reduce the risk for nonintact skin or mucous membranes coming in contact with infected body fluids and blood. Teach everyone the importance of consistently using these safer sex practices:

- A latex or polyurethane condom for genital and anal intercourse (Chart 21-1)

CHART 21-1 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Condom Use to Prevent Sexually Transmitted Diseases

- Use latex or polyurethane condoms rather than natural membrane condoms.
- Store condoms in a cool, dry place.
- Do not use condoms that were in damaged packages or those that show signs of age, such as those that are brittle, sticky, or discolored.
- Handle condoms carefully to avoid puncturing them.
- Put a condom on before making any genital contact.
- Hold the tip of the condom and unroll it onto the erect penis, making sure that no air is trapped in the tip. Leave space at the tip to collect semen.
- Use adequate lubrication. Use water-based lubricants only. Petroleum or oil-based lubricants such as petroleum jelly, cooking oil, shortening, and lotions can damage the condom.
- Replace a broken condom immediately. If ejaculation occurs after the condom breaks, there may be some protection in the immediate use of a spermicide.
- After ejaculation, the condom must remain on until the penis is withdrawn. While the penis is still erect, hold the condom against the base of the penis while withdrawing.
- Never reuse condoms.

From Centers for Disease Control. (1988). Condoms for prevention of sexually transmitted diseases. *Morbidity and Mortality Weekly Report*, 37(9), 133-137.

- A condom or latex barrier (dental dam) over the genitals or anus during oral-genital or oral-anal sexual contact
- Latex gloves for finger or hand contact with the vagina or rectum

A promising area of research for prevention of sexual transmission is the use of vaginal gels that contain an antiretroviral agent (tenofovir or raltegravir). Early results indicate that if the gel is used before and after intercourse, new infections among women can be reduced by as much as 50% (Abdool Karim et al., 2010).

For those who believe they have been exposed to HIV as a result of sexual relations or other types of nonoccupational exposure, the CDC has guidelines for postexposure prophylaxis. The length and type of prophylaxis therapy depend on the nature of the exposure (Chart 21-2).

Parenteral Transmission

Preventive practices to reduce transmission among injection drug users (IDUs) include the use of proper cleaning of “works” (needles, syringes, other drug paraphernalia). Instruct IDUs to clean a used needle and syringe by first filling and flushing them with clear water. Next, the syringe should be filled with ordinary household bleach. The bleach-filled syringe should be shaken for 30 to 60 seconds. Advise IDUs to carry a small container with this solution whenever sharing needles. Some communities have a needle exchange program in which needles and syringes are used only once and are then exchanged for clean ones.

The risk for AIDS transmission through blood and blood products has been reduced to a national average of 0.02%. Several measures are used to protect the nation's blood supply.

CHART 21-2 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Nonoccupational Postexposure Prophylaxis (nPEP) to HIV

Recommendations for nPEP with a *substantial risk* for HIV exposure is a 28-day course of the preferred regimen of HAART*†

NNRTI-based Efavirenz plus either lamivudine or emtricitabine plus either zidovudine or tenofovir

or

PI-based Lopinavir/ritonavir plus either lamivudine or emtricitabine plus zidovudine

A substantial risk is exposure of any of these:

- Vagina
- Rectum
- Eye
- Mouth
- Other intact mucous membrane
- Nonintact skin or mucous membrane

With:

- Blood
- Semen
- Vaginal secretions
- Rectal secretions
- Breast milk
- Any body fluid visibly contaminated with blood

When:

- The source person is known to be HIV-infected

Data from Centers for Disease Control and Prevention. (2005). Antiretroviral postexposure prophylaxis after sexual, injection-drug use, or other nonoccupational exposure to HIV in the United States. *Morbidity and Mortality Weekly Report*, 54(RR-2), 1-27.

HAART, Highly active antiretroviral therapy; NNRTI, non-nucleoside reverse transcriptase inhibitor; PI, protease inhibitor.

*Either when a substantial risk has occurred and more than 72 hours has passed since the exposure or when the exposure is considered to be a negligible risk, nPEP is not recommended.

†When a substantial risk has occurred and less than 72 hours has passed since the exposure but the HIV-infection status of the source person is not known, nPEP is determined on a case-by-case basis.

All donated blood in North America is screened for the HIV antibody, and blood that is positive for HIV antibodies is discarded. Because of the time lag in antibody production (seroconversion) after exposure to HIV, infected blood can test negative for HIV antibodies. False-negative and false-positive results also can occur for other reasons. Inform patients that there is a small but real possibility of HIV transmission through blood and blood products. As a result, methods for reducing transfusion-related infections have included less reliance on standard transfusion therapy through more stringent criteria for transfusion, the use of growth factors to promote more rapid blood production in the patient, and an increase in autologous transfusion in which the patient donates his or her own blood to be transfused back at a later time.

Perinatal Transmission

The risk for perinatal transmission to infants in pregnant patients with HIV infection is about 25% in woman who are not using drug therapy for the disease compared with about 8% for women who are using drug therapy for HIV. Therefore encourage HIV-positive women who are pregnant to

continue the therapy or, if they are not on antiviral therapy, to start the therapy as soon as possible.

HIV transmission can occur across the placenta during pregnancy, with infant exposure to blood and vaginal secretions during birth, or with exposure after birth through breast milk. Inform women of childbearing age with HIV infection about the risks for perinatal transmission. Consult a maternal-child textbook for more information about reducing perinatal transmission of HIV.

Transmission and Health Care Workers

Needle stick or “sharps” injuries are the main means of occupation-related HIV infection for health care workers. In addition, health care workers can be infected through exposure of nonintact skin and mucous membranes to blood and body fluids. Because of the time lag between the time of infection with HIV and the production of serum antibodies (seroconversion), infected people can test negative for HIV and still transmit the virus. *The best prevention for health care providers is the consistent use of Standard Precautions for all patients as recommended by the CDC and required by The Joint Commission (TJC) (see Chapter 25).* Chart 21-3 lists the recommended actions for prevention of HIV infection after a needle stick or other occupational exposure (postexposure prophylaxis [PEP]). When the source patient is known to be HIV negative, PEP is not recommended.

The public may be concerned about HIV transmission by health care workers. Health care workers should wear gloves when in contact with patients' mucous membranes or non-intact skin. Infected workers with weeping dermatitis or open lesions should not perform direct care. The CDC guidelines for preventing HIV transmission by health care workers during exposure-prone invasive procedures are listed in Chart 21-4. These include any procedure in which there is a risk for broken skin injury to the health care worker and the worker's blood is likely to make contact with the patient's body cavity, subcutaneous tissues, or mucous membranes. The purpose of these guidelines is to reduce the risk for HIV transmission to patients.

DECISION-MAKING CHALLENGE

Teamwork and Collaboration; Safety

You have just changed jobs and are working in the day-surgery and procedure center of a large hospital. You recognize from your former place of employment one of the gastroenterologists as a patient who is under treatment for HIV disease. He is performing short procedures, including endoscopy and colonoscopy.

1. Should you approach this surgeon with the knowledge you have about his HIV status? Why or why not?
2. Does performing endoscopies or colonoscopies represent an HIV transmission risk from this surgeon to his patients? Explain your choice.
3. What are your responsibilities in this situation?

Testing

Testing for HIV antibodies or other features of the virus is complex, requiring interpretation, counseling, and confidentiality. Testing plays a role in prevention because tests are a way of diagnosing HIV infection before immune changes or symptoms develop. A primary health care focus for testing is to teach those who test positive to modify their behaviors to

CHART 21-3 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Postexposure Prophylaxis (PEP) for Occupational HIV Exposure*

BASIC PEP†	EXPANDED PEP‡
Small volume (few drops) exposure to mucous membranes or nonintact skin - Source patient is HIV positive, asymptomatic with known low viral load - Source patient is HIV positive, symptomatic or AIDS with high viral load	Large volume (major splash) exposure to mucous membranes or nonintact skin Source patient is HIV positive, symptomatic or AIDS with high viral load
Large volume (major splash) exposure to mucous membranes or nonintact skin - Source patient is HIV positive, asymptomatic with known low viral load - Optional when source patient is unknown or known with HIV risk factors	Less severe percutaneous injury (solid needle or superficial injury) Source patient is HIV positive, symptomatic or AIDS with high viral load
Less severe percutaneous injury (solid needle or superficial injury) - Source patient is HIV positive, asymptomatic with known low viral load - Optional when source patient is unknown or known with HIV risk factors	More severe percutaneous injury (large-bore hollow needle, deep punctures, visible blood on the device, needle was in the patient's artery or vein) - Source patient is HIV positive, asymptomatic with known low viral load - Source patient is HIV positive, symptomatic or AIDS with high viral load

Data from Centers for Disease Control and Prevention. (2005). Updated Public Health Service guidelines for the management of health-care worker exposure to HIV and recommendations for postexposure prophylaxis. *Morbidity and Mortality Weekly Report*, 54(RR-9), 1-22.

*When PEP therapy is instituted, the recommended course is 28 days.

†Basic PEP = Two drugs: (zidovudine plus lamivudine or emtricitabine); or (stavudine plus lamivudine or emtricitabine); or (tenofovir plus lamivudine or emtricitabine).

‡Expanded PEP = Three or more drugs: (zidovudine plus lamivudine or emtricitabine plus lopinavir/ritonavir); or (stavudine plus lamivudine or emtricitabine plus lopinavir/ritonavir); or (tenofovir plus lamivudine or emtricitabine plus lopinavir/ritonavir).

prevent transmission to others. *Therefore all sexually active people should know their HIV status.* Chart 21-5 lists additional conditions for which HIV antibody testing is advised.

Pretest and post-test counseling must be performed by personnel trained in HIV issues. These counselors may be nurses, physicians, social workers, health educators, or even lay educators who have specialized training. Counseling helps the patient make an informed decision about testing and provides an opportunity to teach risk-reduction behaviors. Post-test counseling is needed to interpret the results, discuss risk reduction, and provide psychological support and health promotion information for the patient with a positive test result. People who test positive should also be counseled on how to inform sexual partners and those with whom they have shared needles. Testing methods, their accuracy, and indications are presented on pp. 368-369 in the Laboratory Assessment section.

CHART 21-4 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Recommendations for Preventing HIV Transmission by Health Care Workers

- Workers should adhere to Standard Precautions.
- Workers with exudative lesions or weeping dermatitis should not perform direct patient care or handle patient care equipment and devices used in invasive procedures.
- Workers must follow guidelines for disinfection and sterilization of reusable equipment used in invasive procedures.
- Workers infected with HIV are not restricted from practice of non-exposure-prone procedures, as long as they comply with Standard Precautions and sterilization and disinfection recommendations.
- Workers should identify exposure-prone procedures by institutions where they are performed.
- Workers who perform exposure-prone procedures should know their HIV antibody status.
- Workers who are infected with HIV should seek advice from an expert review panel before performing exposure-prone procedures to determine under what circumstances they may continue to practice these procedures. These circumstances would include notification of prospective patients of HIV positivity.

Modified from Centers for Disease Control. (1991). Recommendations for preventing transmission of human immunodeficiency virus and hepatitis B virus to patients during exposure-prone invasive procedures. *Morbidity and Mortality Weekly Report*, 40(RR-8), 1-9.

CHART 21-5 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

CDC Recommendations for HIV Testing

- You should be tested for HIV if you fall within one or more of these groups:
- People with sexually transmitted disease
 - Injection drug users
 - People who consider themselves at risk
 - Women of childbearing age with identifiable risks, including:
 - Used injection drugs
 - Engaged in prostitution
 - Had sexual partners who were infected or at risk
 - Had contact with men from countries with high HIV prevalence
 - People who received a transfusion between 1978 and 1985
 - People planning to get married
 - People undergoing medical evaluation or treatment for manifestations that may be HIV related
 - People admitted to hospitals
 - People in correctional institutions such as jails and prisons
 - Prostitutes and their customers

Modified from Centers for Disease Control. (1987). Public Health Service guidelines for counseling and antibody testing to prevent HIV infection and AIDS. *Morbidity and Mortality Weekly Report*, 36(31), 509-515. CDC, Centers for Disease Control and Prevention.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

The person who has HIV disease is monitored on a regular basis for changes in immune function or health status that indicate disease progression and warrant prophylaxis or intervention. The frequency of monitoring and reassessment varies from every 2 to 6 months based on disease progression

and responses to treatment. This comprehensive and continuing assessment of the patient with HIV infection is crucial, because he or she may have problems related to disease in many organ systems. Assess subtle changes so that infections and other problems can be found early and treated.

History

Ask specifically about age, gender, occupation, and where the person lives. Thoroughly assess the current illness, including its nature, when it started, the severity of symptoms, associated problems, and any interventions to date. Ask the patient about when the HIV infection was diagnosed and what clinical symptoms led to that diagnosis. Ask him or her to give a chronologic history of infections and clinical problems since the diagnosis. Assess the patient's health history, including whether he or she received a blood transfusion between 1978 and 1985 in the United States (before routine blood testing for HIV contamination). Blood testing for HIV contamination is not consistently performed in all parts of the world and is a source of infection for immigrants. Ask the immigrant patient about his or her history of transfusion therapy before coming to the United States.

Ask the patient about sexual practices, sexually transmitted diseases (STDs), and any major infectious diseases, including tuberculosis and hepatitis. If the patient has hemophilia, ask about treatment with clotting factors. Determine whether the patient has engaged in past or present injection drug use, including needle exposure and needle sharing. Assess the patient's level of knowledge regarding the diagnosis, symptom management, diagnostic tests, treatments, community resources, and modes of HIV transmission. Also assess his or her understanding and use of safer sex practices. If knowledge deficits are found, provide the appropriate patient teaching.

Physical Assessment/Clinical Manifestations

HIV disease and AIDS are a progression continuum. The patient with HIV disease may either have few manifestations and problems or may have problems that are acute rather than chronically present. As the disease progresses, however, more health problems of long duration and greater severity occur. He or she may not realize that the disease is progressing. Assess for manifestations that cluster as symptoms of disease progression and may indicate that the treatment regimen needs to be modified (Chart 21-6).

Opportunistic Infections. The patient with HIV/AIDS often develops pathogenic infections and opportunistic infections. *Pathogenic infections* are caused by virulent organisms and occur even among people whose immune systems are functioning normally. *Opportunistic infections* are those caused by organisms that are present as part of the body's normal environment and are kept in check by normal immune function. Only when immune function is depressed are such organisms capable of causing infection.

Opportunistic infections occur because of the profound immunosuppression of the person with HIV infection. They may result from primary infection or reactivation of a latent infection. Opportunistic infections account for many of the clinical symptoms observed in HIV infection and can be protozoan, fungal, bacterial, or viral. More than one infection may be present at the same time. The presence of opportunistic infections may represent disease progression or a

CHART 21-6 KEY FEATURES

AIDS

Immunologic Manifestations

- Low white blood cell counts:
 - CD4+/CD8+ ratio <2
 - CD4+ count <200/mm³
- Hypergammaglobulinemia
- Opportunistic infections
- Lymphadenopathy
- Fatigue

Integumentary Manifestations

- Dry skin
- Poor wound healing
- Skin lesions
- Night sweats

Respiratory Manifestations

- Cough
- Shortness of breath

Gastrointestinal Manifestations

- Diarrhea
- Weight loss
- Nausea and vomiting

Central Nervous System Manifestations

- Confusion
- Dementia
- Headache
- Fever
- Visual changes
- Memory loss
- Personality changes
- Pain
- Seizures

Opportunistic Infections

- Protozoal infections
 - *Pneumocystis jiroveci* pneumonia
 - Toxoplasmosis
 - Cryptosporidiosis
 - Isosporiasis
 - Microsporidiosis
 - Strongyloidiasis
 - Giardiasis
- Fungal infections
 - Candidiasis
 - Cryptococcosis
 - Histoplasmosis
 - Coccidioidomycosis
- Bacterial infections
 - *Mycobacterium avium* complex infection
 - Tuberculosis
 - Nocardiosis
- Viral infections
 - Cytomegalovirus infection
 - Herpes simplex virus infection
 - Varicella-zoster virus infection

Malignancies

- Kaposi's sarcoma
- Non-Hodgkin's lymphoma
- Hodgkin's lymphoma
- Invasive cervical carcinoma

temporary further reduction of immune status. *In either case, these infections can result in death if appropriate treatment is not started quickly.* Priority nursing actions when caring for a patient who is HIV positive are continually assessing for the presence of an opportunistic infection and monitoring the patient's response to therapy. Document all assessment findings in the patient's medical record, and report to the health care provider those manifestations that may indicate an infection.

Opportunistic infections do not pose a threat to the immunocompetent health care worker caring for a patient with HIV infection or AIDS. When the patient with HIV infection or AIDS has a pathogenic infection, however, health care personnel must use precautions appropriate to the specific disease to prevent disease spread. For example, when the person with HIV/AIDS also has tuberculosis at a transmissible stage, Airborne Precautions are needed in addition to Standard Precautions. See Chapter 25 for a more complete discussion on Transmission-Based Precautions for specific infectious diseases.

Protozoal infections are common among patients with AIDS. *Pneumocystis jiroveci* pneumonia (PCP) (at one time thought to be the protozoa *Pneumocystis carinii*) is the most common opportunistic infection in persons infected with HIV. This organism is considered a protozoa by some scientists and a fungus by others. Assess for dyspnea on exertion, tachypnea, a persistent dry cough, and fever (usually low-grade and persistent). The patient with PCP may report fatigue and weight loss. Listen to breath sounds for crackles that may be present on lung auscultation.

Toxoplasmosis encephalitis, caused by *Toxoplasma gondii*, is acquired through contact with contaminated cat feces or by ingesting infected, undercooked meat. Assess the patient for subtle changes in mental status, neurologic deficits, headaches, and fever. Other symptoms to assess include difficulties with speech, gait, and vision; seizures; lethargy; and confusion. Perform a comprehensive baseline mental status examination and monitor the patient to detect subtle changes.

Cryptosporidiosis is an intestinal infection caused by *Cryptosporidium* organisms. In AIDS, this illness ranges from a mild diarrhea to a severe wasting with electrolyte imbalance. Diarrhea may result in fluid loss of up to 15 to 20 L/day. Ask the patient about the presence of diarrhea and whether he or she has had an unplanned weight loss of 5 pounds or more.

Fungal infections occur by overgrowth of normal body flora. *Candida albicans* is part of the natural flora of the intestinal tract. In the person with AIDS, candidiasis (overgrowth of the *Candida* fungus) occurs because the weakened immune system can no longer control fungal growth. *Candida* stomatitis or esophagitis is a frequent finding in AIDS. Patients may report food tasting "funny," mouth pain, difficulty in swallowing, and retrosternal pain (pain behind the sternum). On examination of the mouth and the back of the throat, you may see cottage cheese–like, yellowish white plaques and inflammation (Fig. 21-6). Esophagitis is diagnosed by endoscopic biopsy and culture. Women with HIV disease or AIDS may have persistent vaginal candidiasis with severe pruritus (itching), perineal irritation, and a thick, white vaginal discharge.

Cryptococcosis is a debilitating meningitis and is sometimes a widely spread infection in AIDS. It is caused by *Cryptococcus neoformans*. Ask about fever, headache, blurred vision, nausea and vomiting, nuchal rigidity (stiff neck), mild

FIG. 21-6 Oral candidiasis (thrush).

confusion, and other mental status changes. Some patients have seizures and other focal neurologic problems, or they may have mild symptoms of malaise and fever with or without headaches.

Histoplasmosis, caused by *Histoplasma capsulatum*, begins as a respiratory infection and progresses to widespread infection in the person with AIDS. Assess whether dyspnea, fever, cough, and weight loss are present. Check for enlargement of lymph nodes, the spleen, or the liver.

Bacterial infections are acquired from other people or sources and as overgrowth of skin flora. *Mycobacterium avium* complex (MAC) is the most common bacterial infection associated with AIDS. This problem is caused by *M. intracellulare* or *M. avium*, which infects the respiratory or GI tract. MAC is a systemic infection. Positive cultures may be obtained from lymph nodes, bone marrow, and blood. Assess for fever, debility, weight loss, malaise, and sometimes swollen lymph glands or organ disease.

Tuberculosis (TB), caused by *Mycobacterium tuberculosis*, occurs in 2% to 10% of persons with AIDS (CDC, 2009a). More than 50% of all patients with AIDS and TB have extrapulmonary disease sites, including the central nervous system, bones, liver, spleen, skin, and intestinal tract. Ask about the presence of cough, dyspnea, chest pain, fever, chills, night sweats, weight loss, and anorexia. Symptoms of extrapulmonary infection vary with the site. *The person with TB and a CD4+ T-cell count below 200/mm³ may not have a positive TB skin test (purified protein derivative [PPD]) because of an inability to mount an immune response to the antigen, a condition known as anergy.* Blood analysis by an interferon release gamma assay (IRGA) using the commercial test QuantiFERON-TB Gold (QFT-G) is the most sensitive and rapid test for the presence of *M. tuberculosis* (Diel et al.,

! NURSING SAFETY PRIORITY

Action Alert

Until parameters other than a skin test come back negative for TB in a patient with AIDS who also has TB symptoms, maintain Airborne Precautions along with Standard Precautions.

2009). Results are ready in 24 hours. Although this test is not recommended for mass or public health screening, it is very useful in the acute care setting to determine whether a symptomatic patient actually has TB. Other diagnostic tests include a chest x-ray, acid-fast sputum smear, and sputum culture.

The tuberculosis bacillus is spread by airborne routes. When particles from the patient's respiratory tract are aerosolized, anyone near him or her is at risk for inhaling the particles and the bacillus. Therefore the nurse or respiratory therapist who gives cough-inducing aerosol treatments, such as pentamidine isethionate, to patients with AIDS should be screened with a PPD skin test every 6 months to determine whether he or she has been infected with TB.

Pneumonia from bacterial infections recurs often among patients with AIDS. In the current CDC classification system for AIDS, two or more episodes of any type of bacterial pneumonia in a 12-month period are an AIDS case definition. Assess for chest pain, productive cough, fever, and dyspnea.

Viral infection from a virus other than HIV is common among people with HIV disease that has progressed to AIDS. Cytomegalovirus (CMV) can infect many sites in persons with AIDS, including the eye (CMV retinitis), respiratory and GI tracts, and the central nervous system. CMV infection can also cause many nonspecific problems such as fever, malaise, weight loss, fatigue, and swollen lymph nodes. CMV retinitis impairs vision, ranging from slight impairment to total blindness. CMV can also cause diarrhea, abdominal bloating and discomfort, and weight loss. Ask the patient whether he or she has any of these manifestations. In addition, CMV can cause encephalitis, pneumonitis, adrenalitis, hepatitis, and disseminated infection.

Herpes simplex virus (HSV) infections in people with HIV disease or AIDS occur in the perirectal, oral, and genital areas. The manifestations are more widespread and of longer duration among patients with HIV/AIDS than among those who are immunocompetent. Numbness or tingling at the site of infection occurs up to 24 hours before blisters form. Lesions are painful, with chronic open areas after blisters rupture. Assess for fever, pain, bleeding, and lymph node enlargement in the affected area. Other manifestations include headache, myalgia, and malaise.

Varicella-zoster virus (VZV) infection (*shingles*) is not a new infection for people with AIDS. This virus, present in the nerve ganglia of many people, causes chickenpox. When people who have had chickenpox previously are immunocompromised, VZV leaves the nerve ganglia and enters body fluids and other tissue areas, causing shingles. Ask whether the patient has pain and burning along sensory nerve tracts (see [Chapter 43](#) for the dermatomes of sensory nerve locations). Examine the skin for fluid-filled blisters with or without crusts. Other problems include headache and low-grade fever.

Malignancies. The weakened immune response increases the risk for some cancers. These include Kaposi's sarcoma, lymphomas, invasive cervical cancer, lung cancer, GI cancers, and anal cancer (Kirton, 2011).

Kaposi's sarcoma (KS) is the most common AIDS-related malignancy, occurring in 1% to 21% of patients with AIDS. The risk for KS appears to be related to co-infection with human herpes virus-8.

KS develops as small, purplish brown, raised lesions that are usually not painful or itchy. The lesions can occur

FIG. 21-7 Kaposi's sarcoma lesions.

anywhere on the body ([Fig. 21-7](#)). Most patients with KS have skin or mucous membrane lesions. In some patients, lesions develop in the lymph nodes, mouth and throat, intestinal tract, or lungs. KS is diagnosed by biopsy and histologic examination of the lesion. Assess KS lesions for number, size, location, and whether they are intact, and monitor their progression.

Malignant lymphomas occurring with AIDS are Hodgkin's lymphoma, non-Hodgkin's B-cell lymphomas, such as Burkitt's lymphoma, immunoblastic lymphoma, and primary brain lymphoma. Manifestations include swollen lymph nodes, weight loss, fever, and night sweats.

Endocrine Complications. Patients with HIV disease may have disease-related endocrine problems, such as gonadal dysfunction, body shape changes, adrenal insufficiency, diabetes mellitus, and elevated triglycerides and cholesterol ([Table 21-2](#)).

Many HIV-positive men have low testosterone levels, and HIV-positive women often have irregular menstrual cycles. With this gonadal dysfunction comes a decrease in body muscle mass for both genders, with a decrease in weight, and a change in libido, accompanied by a decrease in energy and an increase in fatigue.

Body shape changes from fat redistribution or lipodystrophy are common in patients receiving antiretroviral therapies, especially protease inhibitors and nucleoside analog reverse transcriptase inhibitors. Manifestations include "buffalo humps" or cervical (neck) fat development and large abdominal fat accumulations. Other body areas, such as the face, arms, and legs, have a wasted appearance and show prominent vein patterns from loss of subcutaneous fat.

Adrenal dysfunction can result from the glands being infected by opportunistic infections (cytomegalovirus, *M. avium*, or *M. tuberculosis*), resulting in adrenal insufficiency. This problem manifests as fatigue, weight loss, nausea, vomiting, low blood pressure, and electrolyte disturbances and can be life threatening.

Patients taking protease inhibitors have a higher-than-expected incidence of type 1 diabetes and hyperlipidemia. These problems are seen even among patients who have no other risks for these problems or the associated heart disease.

Other Clinical Manifestations. All body systems are affected to some degree in AIDS.

TABLE 21-2 ENDOCRINE COMPLICATIONS OF HIV INFECTION OR TREATMENT

ENDOCRINE GLAND	PROBLEMS/DYSFUNCTION
Gonads	Decreased testosterone
	Reduced libido
	Increased fatigue
	Reduced fertility
	Decreased muscle mass
	Weight loss
	Decreased estrogen
	Reduced libido
	Premature menopause
	Decreased muscle mass
Adrenal cortex	Increased cortisol
	Fat redistribution
	Decreased muscle mass
	Decreased cortisol
	Adrenal insufficiency
	Hypoglycemia
	Hyperkalemia
	Hypotension
	Fatigue
	Weight loss
Pancreas	Reduced exocrine function
	Fatty food intolerance
	Cholelithiasis
	Pancreatitis
	Reduced endocrine function
	Diabetes mellitus
	Hyperlipidemia

AIDS dementia complex (ADC), also called *HIV-associated dementia complex*, refers to the manifestations of central nervous system involvement. ADC occurs in about 70% of people with AIDS. It is a result of infection of cells within the central nervous system by HIV. ADC causes cognitive, motor, and behavioral impairments. Manifestations range from barely noticeable to severe dementia. (See [Chapter 44](#) for more discussion on dementia.)

Some neurologic problems may be a result of HIV infection or drug side effects, including peripheral neuropathies and myopathies. Assess for symptoms of peripheral neuropathies, which include paresthesias and burning sensations, reduced sensory perception, pain, and gait changes. Myopathies are accompanied by leg weakness, ataxia, and muscle pain.

AIDS wasting syndrome is not due to any single factor. It may be a result of altered metabolism from cancer or infection. Diarrhea, malabsorption, anorexia, and oral and esophageal lesions can all contribute to persistent and sometimes extreme weight loss, and the patient may appear quite emaciated.

Skin changes include dry, itchy, irritated skin and many types of rashes. Folliculitis, eczema, or psoriasis may occur. Ask the patient about skin sensation changes, and examine any rash or irritation. When the platelet count is low, petechiae or bleeding gums may be present.

Psychosocial Assessment

Psychosocial data collection for a patient with AIDS is very important. Ask about the patient's social support system, including family, significant others, and friends. To protect confidentiality, learn who in this support system is aware of

the diagnosis so that it is not inadvertently mentioned. Some patients, because of fear of discrimination, are quite selective about whom they tell. Health care professionals must respect the patient's choices as much as possible without compromising care. Offer resources to help with disclosure to sexual partners or significant others.

The patient may be closest to a lover or a friend who is not legally recognized as next of kin. Obtain the name and telephone number of that person, and learn whether a health care proxy or durable power-of-attorney document has been signed.

Ask about the patient's ADLs, as well as any changes that may have occurred since the diagnosis. Also assess his or her employment status and occupation, immigration status, social activities and hobbies, living arrangements, and financial resources, including health insurance. Also ask whether he or she uses drugs, including tobacco, alcohol, supplements, opioids, benzodiazepines, cocaine, or crystal methamphetamine.

To plan care and monitor changes, assess the patient's anxiety level, mood, cognitive ability, and level of energy. Ask about any experiences with discrimination and how they were handled. After assessing the patient's level of self-esteem and changes in body image, work with him or her to identify strengths and coping strategies. Gather information about any suicidal ideation, depression, or other psychological problems. Also ask about the use of support groups or other community resources.

The patient with HIV infection has less energy as the disease progresses. Many factors contribute to this energy loss, and many cannot be treated. Pace interviews, assessments, and intervention activities to match his or her energy level. When the patient is greatly fatigued, postpone or eliminate nonurgent tests or care activities.

Laboratory Assessment

Lymphocyte Counts. Lymphocyte counts are performed as part of a complete blood count (CBC) with differential (see [Chapter 19](#)). The normal white blood cell (WBC) count is between 5000 and 10,000 cells/mm³, with a differential of about 30% to 40% lymphocytes (an absolute number of 1500 to 4500). Patients with AIDS are often leukopenic, with a WBC count of less than 3500 cells/mm³, and lymphopenic (<1500 lymphocytes/mm³).

CD4+ T-cell and CD8+ T-cell counts and percentages are an important part of an immune profile. People with HIV disease usually have a lower-than-normal number of CD4+ T-cells. Some patients with AIDS have fewer than 100 cells/mm³ (normal: 500 to 1500 cells/mm³), whereas the number of CD8+ T-cells remains normal. The normal ratio of CD4+ to CD8+ T-cells is 2:1. In HIV disease and AIDS, because of the low number of CD4+ T-cells, this ratio is low. Low CD4+ T-cell counts and a low ratio are associated with increased manifestations of disease.

Antibody Tests. Antibody tests are used to measure the patient's response to the virus (the antigen) rather than to measure parts of the virus. When the body is infected with HIV, the normal response is to make an antibody to the infecting agent. This antibody is usually made 3 weeks to 3 months after the infection first occurs, although in some people, antibodies are not made until 36 months after initial infection.

Thus antibody tests for HIV antibody can be measured by enzyme-linked immunosorbent assay (ELISA) and Western blot analysis. False-negative results (incorrectly indicating the absence of HIV infection) have been reported early in the infection, in people with cancer, and in people receiving long-term immunosuppressive therapy.

ELISA is an inexpensive and accurate test. The patient's serum is mixed with HIV grown in culture. If the patient has antibodies to HIV, they bind to the HIV antigens and can be detected (a positive test). However, this test can be negative even when the person has HIV infection if the test is performed before antibodies are made in sufficient amounts. The time between when a person is first infected with the virus and when viral replication is occurring but the immune system has not yet started making antibodies is called the "window period." *This means that if the patient has an episode of unprotected sex with an HIV-positive person one night and comes in for testing a week later, the ELISA will be negative even though the patient may have active HIV. Thus testing during the window does not provide useful information.*

False-positive test results (incorrectly indicating HIV infection) occur in about 0.1% (1 of 1000) of those tested with ELISA. False-positive results sometimes occur in pregnant women and women who have had children, injection drug users, people who have had malaria, patients with lymphomas, and other conditions. Therefore anyone who has a positive ELISA needs to have additional testing to confirm or rule out infection.

Western blot is used to confirm the diagnosis when the results of an ELISA are positive. This test is more sophisticated and expensive than the ELISA. The Western blot detects serum antibodies to four specific major HIV antigens. A positive Western blot result is based on the presence of antibodies to at least two of the major HIV antigens.

The result is considered inconclusive if two of the major antibodies are not detected but other antibodies to HIV are. The person should then be retested. *If a person has a positive test result for HIV antibodies, it does not mean that he or she has AIDS—only that he or she has been infected with the virus.*

Both the ELISA and Western blot are blood-based tests. This requires special equipment and trained personnel to test for HIV infection. Some HIV testing is simpler, using techniques that are not blood-based so that testing can be done anywhere, even at home. One test involves oral testing for HIV antibody. This test uses a device that is placed against the gum and cheek for 2 minutes. Fluid (not saliva) is drawn into an absorbable pad, which, in an HIV-positive person, contains HIV-specific antibodies. The pad is placed in a solution; a positive result shows a change similar to a positive result in a urine pregnancy test. Total testing time is about 20 minutes. This test has the same accuracy as blood testing and can provide results quickly. If results are positive for HIV, a blood test is needed to confirm the result.

Home test kits require that a drop of blood be placed on a test card with a special code number. The card is mailed to a laboratory where the blood is tested for HIV antibodies. A special telephone number is called and the code entered. Test results are then given.

Viral Load Testing. **Viral load testing** (also called *viral burden testing*) measures the presence of HIV viral genetic material (RNA) or other viral proteins in the patient's blood rather than the body's response to the virus. These tests are

quantitative and indicate the level of viral burden or viral load. Such tests are useful in monitoring disease progression and treatment effectiveness.

Quantitative RNA assays are used for quantitative viral load testing. These assays include the reverse transcriptase–polymerase chain reaction (RT-PCR), the branched DNA (bDNA) method, and the nucleic acid sequence-based assay (NASBA). All three assays use gene amplification to determine the amount of HIV RNA present in a patient's serum, and all have a specificity of 100%. Even if only a few infected cells are present in a serum sample, tiny amounts of the HIV RNA are amplified by these methods to allow detection and diagnosis of people who have no indication of infection. These tests are used to monitor therapy effectiveness and as indicators of the need to change drug regimens.

Other Laboratory Assessment. Other laboratory tests monitor the overall health of the patient and detect or diagnose any infections or other problems related to HIV disease. These tests include blood chemistries, a CBC with differential and platelets, toxoplasmosis antibody titer, liver function tests, a serologic test for syphilis (STS), and antigens to hepatitis A, hepatitis B, and hepatitis C. Tests to further evaluate the immune profile of a patient may include bone marrow aspiration with biopsy and cultures. In addition, other tests may be performed to monitor toxicities related to antiretroviral drug therapy.

GENETIC/GENOMIC CONSIDERATIONS

The HIV genotype test is used to determine whether any mutations exist in the strain of HIV that has infected the patient. This test is useful before starting antiretroviral therapy to learn whether the patient is infected with a resistant strain of HIV. If so, the test will help the clinician choose which antiretroviral drugs are likely to be effective against viral replication and to which drugs the virus is resistant. It is also useful in patients who are started on antiretroviral therapy and demonstrate an initial success, but then develop rapid disease progression.

The HLA *B5701* allele test is a genetic test to determine how a person will respond to a drug. For example, about 3% to 8% of patients who take abacavir (Ziagen) have a hypersensitivity reaction to it that ranges from mild fever, rash, nausea, and vomiting to fatal anaphylaxis. The *B5701* allele is a genetic variation that is strongly associated with abacavir hypersensitivity, although it does not predict how severe a hypersensitivity reaction will be. Abacavir should not be used without first testing for *B5701*, and if positive, abacavir is never used either as an individual drug or in combined drug preparations.

Other Diagnostic Assessment

Other diagnostic tests are performed on the basis of the patient's manifestations. Such tests may include testing stool for ova and parasites; biopsies of the skin, lymph nodes, lungs, liver, GI tract, or brain; a chest x-ray; gallium scans;

NCLEX EXAMINATION CHALLENGE

Health Promotion and Maintenance

Which finding in the client with HIV disease who is receiving antiretroviral therapy indicates to the nurse that the treatment is effective?

- A. CD4+ cells 700/mm³
- B. CD4+ cells 200/mm³
- C. CD8+ cells 700/mm³
- D. CD8+ cells 200/mm³

bronchoscopy, endoscopy, or colonoscopy; liver and spleen scans; computed tomography (CT) scans; pulmonary function tests; and arterial blood gas (ABG) analysis.

ANALYSIS

The priority problems for patients with AIDS are:

1. Potential for infection related to immune deficiency
2. Inadequate oxygenation related to anemia, respiratory infection (*P. jiroveci* pneumonia [PCP], cytomegalovirus [CMV] pneumonitis), pulmonary Kaposi's sarcoma (KS), or anemia
3. Pain related to neuropathy, myelopathy, cancer, or infection
4. Inadequate nutrition related to high metabolic need, nausea and vomiting, diarrhea, difficulty chewing or swallowing, or anorexia
5. Diarrhea related to infection, food intolerance, or drugs
6. Reduced skin integrity related to KS, infection, altered nutritional state, incontinence, immobility, hyperthermia, or cancer
7. Confusion related to AIDS dementia complex (ADC), central nervous system infection, or cancer
8. Reduced self-esteem related to changes in body image, role, or independence
9. Potential loss of social contact related to stigma, virus transmissibility, infection control practices, or fear

PLANNING AND IMPLEMENTATION

Preventing Infection

The patient with AIDS is susceptible to opportunistic infections and other infections because of immune deficiency secondary to HIV infection. The initial focus of management is maintaining and supporting the patient's immune function by controlling the HIV infection with antiretroviral therapy. When the patient's immune function declines, management includes both prophylaxis and active treatment of opportunistic infections. Some of these therapies are described under the collaborative care of other priority patient problems.

Planning: Expected Outcomes. The patient is expected to remain free of opportunistic diseases and other infections. Indicators include the following:

- Absence of chills, fever, or temperature instability
- Absence of purulent drainage or sputum
- Absence of diarrhea
- Absence of chest x-ray infiltration
- Maintenance of white blood cell (WBC) count within the patient's normal range

Interventions. The person who has HIV infection and is immunocompromised is at greater risk for any type of infection. Teach him or her to avoid exposure to infection (Chart 21-7). Chart 21-8 outlines best practices for prevention of infection in a hospitalized immunosuppressed patient. Some strategies are investigational, including drug therapy and immune function enhancement.

Drug Therapy. Some drugs have demonstrated antiretroviral effects; however, *it is important to remember that antiretroviral therapy only inhibits viral replication and does not kill the virus.* Treatment with only one antiretroviral agent, known as *monotherapy*, promotes drug resistance and does not improve the duration or quality of life for the patient with HIV/AIDS. Instead, multiple drugs are used together in

CHART 21-7 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Prevention of Infection

During the times when your white blood cell counts are low:

- Avoid crowds and other large gatherings of people who might be ill.
- Do not share personal toilet articles, such as toothbrushes, toothpaste, washcloths, or deodorant sticks, with others.
- If possible, bathe daily, using an antimicrobial soap. If total bathing is not possible, wash the armpits, groin, genitals, and anal area twice a day with an antimicrobial soap.
- Clean your toothbrush at least weekly by either running it through the dishwasher or rinsing it in liquid laundry bleach (and then rinsing out the bleach with hot running water).
- Wash your hands thoroughly with an antimicrobial soap before you eat or drink, after touching a pet, after shaking hands with anyone, as soon as you come home from any outing, and after using the toilet.
- Avoid eating salads; raw fruit and vegetables; undercooked meat, fish, and eggs; and pepper and paprika.
- Wash dishes between use with hot, sudsy water, or use a dishwasher.
- Do not drink water, milk, juice, or other cold liquids that have been standing for longer than an hour.
- Do not reuse cups and glasses without washing.
- Do not change pet litter boxes. If unavoidable, use gloves and wash hands immediately.
- Avoid turtles and reptiles as pets.
- Do not feed pets raw or undercooked meat.
- Take your temperature at least once a day and whenever you do not feel well.
- Report any of the following signs or symptoms of infection to your physician immediately:
 - Temperature greater than 100° F (38° C)
 - Persistent cough (with or without sputum)
 - Pus or foul-smelling drainage from any open skin area or normal body opening
 - Presence of a boil or abscess
 - Urine that is cloudy or foul smelling or that causes burning on urination
- Take all prescribed drugs.
- Do not dig in the garden or work with houseplants.
- Wear a condom (if you are a man) when having sex. If you are a woman having sex with a male partner, ensure that he wears a condom.
- Avoid travel to areas of the world with poor sanitation or less-than-adequate health care facilities.

regimens popularly called “cocktails.” These regimens consist of combinations of different types of antiretroviral agents. This approach is termed *highly active antiretroviral therapy (HAART)* and is showing good results as measured by reduced viral load and improved CD4+ T-cell counts.

An important issue with HAART is the development of drug-resistant mutations in the HIV organism. When resistance develops, viral replication is no longer suppressed by the drugs. Testing is now possible to determine whether a strain of HIV has developed resistance to specific drugs (see the Genetic/Genomic Considerations box on p. 369). Several factors contribute to the development of drug resistance to HAART, with the most important being missed doses of drugs. When doses are missed, the blood drug concentrations become lower than what are needed for inhibition of viral replication

CHART 21-8 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Care of the Hospitalized Immunosuppressed Patient

- Place the patient in a private room whenever possible.
- Use good handwashing technique or use alcohol-based hand rubs before touching the patient or any of his or her belongings.
- Ensure that the patient's room and bathroom are cleaned at least once each day.
- Do not use supplies from common areas for neutropenic patients. For example, keep a dedicated box of disposable gloves in his or her room and do not share this box with any other patient. Provide single-use food products, individually wrapped gauze, and other individually wrapped items.
- Limit the number of health care personnel entering the patient's room.
- Monitor vital signs, including temperature, every 4 hours.
- Inspect the patient's mouth at least every 8 hours.
- Inspect the patient's skin and mucous membranes (especially the anal area) for the presence of fissures and abscesses at least every 8 hours.
- Inspect open areas, such as IV sites, every 4 hours for manifestations of infection.
- Change gauze-containing wound dressings daily.
- Obtain specimens of all suspicious areas for culture (as specified by the agency), and promptly notify the physician.
- Assist the patient in performing coughing and deep-breathing exercises.
- Encourage activity at a level appropriate for the patient's current health status.
- Keep frequently used equipment in the room for use with this patient only (e.g., blood pressure cuff, stethoscope, thermometer).
- Limit visitors to healthy adults.
- Use strict aseptic technique for all invasive procedures.
- Avoid the use of indwelling urinary catheters.
- Keep fresh flowers and potted plants out of the patient's room.
- Teach the patient to eat a low-bacteria diet (e.g., avoiding raw fruits and vegetables; undercooked meat, eggs, and fish; pepper and paprika as seasonings sprinkled on food right before eating).

(often called the *inhibitory concentration*). When this concentration is too low, the organism can replicate and produce new organisms that are resistant to the drugs being used.

An important understanding about HIV resistance to one or more drugs is that once a patient has HIV organisms with resistant mutations, the organisms with the mutations are stored in the body indefinitely. The resistant organisms are most likely in the lymph nodes and spleen, a process known as *archiving*. The drug or drugs to which the virus is resistant are no longer used for that patient. Even years later, if the drug to which the HIV demonstrated resistance is tried again, the viruses with the resistant mutation come out of archival storage to defeat the drug.

! NURSING SAFETY PRIORITY

Drug Alert

Ensure that HAART drugs are not missed, delayed, or administered in lower-than-prescribed doses in the inpatient setting. Teach patients the importance of taking their drugs exactly as prescribed to maintain the effectiveness of HAART drugs. Even a few missed doses per month can promote drug resistance.

The main actions of each drug category are explained below. Representative drugs in each category are presented in [Chart 21-9](#). Drawbacks to HIV/AIDS drug therapy include the expense of the drugs, side effects, food and timing requirements, and the number of daily drugs. The daily regimen is lifelong and burdensome.

Nucleoside analog reverse transcriptase inhibitors (NRTIs) are drugs that have a similar structure to the four nucleoside bases of DNA (adenine, guanine, cytosine, and thymidine), making them “counterfeit” bases. HIV must turn its viral RNA into a double-stranded DNA copy using the enzyme *reverse transcriptase*. This class of drugs “fools” reverse transcriptase into using these counterfeit bases so that poor viral DNA is formed and is not inserted into the host cell's DNA. As a result, viral DNA synthesis and replication are suppressed. This class of anti-HIV agents includes zidovudine (Retrovir), didanosine (ddI, Videx), lamivudine (Epivir, 3TC), stavudine (d4T, Zerit), tenofovir (Viread), emtricitabine (Emtriva), and abacavir (Ziagen).

Non-nucleoside reverse transcriptase inhibitors (NNRTIs) are HIV-specific drugs that work by inhibiting reverse transcriptase. These drugs suppress viral replication but do not kill the virus. These drugs include nevirapine (Viramune), delavirdine (Rescriptor), efavirenz (Sustiva), and etravirine (Intelence). Common problems with this class of drugs include many interactions with other drugs and hypersensitivity reactions.

Protease inhibitors (PIs) are HIV-specific drugs that block the HIV protease enzyme, preventing viral replication and release of viral particles. The HIV initially produces all of its proteins, including the ones needed to move viral particles out of a cell, in one long strand. For the proteins to be active, this large protein must be broken down into separate smaller proteins by HIV protease, which acts like chemical scissors. If this enzyme is inhibited, viral proteins are not functional and viral particles cannot leave the cell to infect other cells. The protease inhibitor drugs, when taken into an HIV-infected cell, make the protease enzyme work on the drug rather than on the initial large protein. Thus active proteins are not produced, and the viral particles cannot leave the cell to infect other cells. Drugs include ritonavir (Norvir), indinavir (Crixivan), saquinavir (Invirase), nelfinavir (Viracept), lopinavir/ritonavir (Kaletra), atazanavir/ritonavir (Reyataz), fosamprenavir (Lexiva), and darunavir/ritonavir (Prezista), and tipranavir (Aptivus). (Placing low doses of ritonavir in combination with other PIs boosts the levels of other PIs, resulting in more effective drug responses at lower drug dosages, fewer side effects, and improved patient adherence.)

Fusion inhibitors work by blocking the fusion of HIV with a host cell by blocking the ability of gp41 to fuse with the host cell's CD4 receptor. Without fusion, infection of new cells does not occur. The current drug in this category is enfuvirtide (Fuzeon), which is administered as a subcutaneous injection.

Entry inhibitors are a relatively new type of anti-HIV drug. The current drug in this category is maraviroc (Selzentry). This drug works to prevent infection by blocking the CCR5 receptor on CD4+ T-cells. Remember, in order for HIV to enter the cell, the virus' gp120 must bind to the CD4 receptor and its gp41 must bind to the CCR5 receptor or to the CXCR4 receptor (see [Fig. 21-3](#)). Viral binding to both receptors is

CHART 21-9 COMMON EXAMPLES OF DRUG THERAPY

HIV Infection

DRUG/ USUAL DOSE (FOR ADULTS WEIGHING >60 kg)	PHYSIOLOGIC PURPOSE	NURSING INTERVENTIONS	RATIONALE
Nucleoside Analog Reverse Transcriptase Inhibitors (NRTIs)			
Abacavir (Ziagen) 300 mg two times daily or 600 mg once daily	Generates bad nucleoside/nucleotide building blocks for HIV	Ensure HLA B5701 allele testing is performed and results are known before the drug is first administered. Instruct the patient that this drug may be taken with or without food.	People who have a specific variation of this gene allele have a high risk for hypersensitivity reactions to this drug. Fewer dietary restrictions increase adherence to drug regimen.
Tenofovir (Viread) 300 mg once daily	Generates bad nucleoside/nucleotide building blocks for HIV	Instruct the patient that this drug may be taken with or without food. Check serum phosphate.	Fewer dietary restrictions increase adherence to drug regimen.
Emtricitabine (Emtriva) 200 mg once daily Very similar in structure and function to lamivudine	Generates bad nucleoside/nucleotide building blocks for HIV Has activity against hepatitis B, useful in Hep B and HIV co-infection	Instruct the patient that this drug may be taken with or without food. Check kidney function tests and GFR and report abnormal findings.	Hypophosphatemia is a common side effect of this drug. Fewer dietary restrictions increase adherence to drug regimen. Drug dose needs to be adjusted (lower) when kidney function is reduced.
Lamivudine (Epivir) 150 mg twice daily or 300 mg once daily Very similar in structure and function to emtricitabine	Generates bad nucleoside/nucleotide building blocks for HIV Has activity against hepatitis B, useful in Hep B and HIV co-infection	Instruct the patient that this drug may be taken with or without food. Check kidney function tests and GFR and report abnormal findings.	Fewer dietary restrictions increase adherence to drug regimen. Drug dose needs to be adjusted (lower) when kidney function is reduced.
Stavudine (Zerit) 40 mg twice daily	Generates bad nucleoside/nucleotide building blocks for HIV	Instruct the patient that this drug may be taken with or without food. Monitor for abdominal pain, nausea, vomiting. Monitor for numbness and tingling in toes/feet. Monitor for body shape changes.	Fewer dietary restrictions increase adherence to drug regimen. Pancreatitis is a common side effect of this drug. Peripheral neuropathy is a common side effect of this drug. Lipodystrophy is a common side effect of this drug.
Didanosine (Videx EC) 400 mg once daily 250 mg once daily if used with tenofovir	Generates bad nucleoside/nucleotide building blocks for HIV	Instruct patients to take this drug 30 min before meals or 2 hours after meals. Monitor for abdominal pain, nausea, vomiting. Monitor for numbness and tingling in toes/feet. Monitor for body shape changes.	Gastric acid destroys the drug's activity.
Zidovudine (Retrovir) 300 mg twice daily	Generates bad nucleoside/nucleotide building blocks for HIV	Instruct the patient that this drug may be taken with or without food. Monitor CBC and check for headache, fatigue, muscle aches.	Pancreatitis is a common side effect of this drug. Peripheral neuropathy is a common side effect of this drug. Lipodystrophy is a common side effect of this drug. Fewer dietary restrictions increase adherence to drug regimen. Marrow suppression is a common side effect of this drug and increases the risk for infection.
Non-Nucleoside Reverse Transcriptase Inhibitor (NNRTI) Class			
Efavirenz (Sustiva) 600 mg once daily	Inhibits reverse transcriptase	Check all co-administered drugs. Monitor for headache, nightmares, vertigo. Assess for rash, fever. Check liver function tests. Determine whether female patients are pregnant. Instruct patients to take the drug on an empty stomach, at bedtime.	This drug interacts with many other drugs, increasing the risk for serious drug side effects. These side effects are common but often resolve within 2 weeks. The drug can cause allergic reactions. The drug is liver toxic and can cause elevations in transaminases. The drug is pregnancy category D and can induce birth defects. Food increases absorption/side effects, CNS effects less pronounced if sleeping.

Nevirapine (Viramune) 200 mg once daily for 2 weeks, then twice daily	Inhibits reverse transcriptase	Check all co-administered drugs. Assess for rash, fever. Check liver function tests. Instruct the patient that this drug may be taken with or without food.	This drug interacts with many other drugs, increasing the risk for serious drug side effects. The drug can cause allergic reactions. The drug is liver toxic and can cause elevations in transaminases. Fewer dietary restrictions increase adherence to drug regimen.
Protease Inhibitor (PI) Class Atazanavir (Reyataz) 300 mg once daily; if the patient has been on a HAART regimen, ritonavir 100 mg daily is needed to maximize the drug's effect. 400 mg of atazanavir may be prescribed once daily if the patient has not previously been taking a HAART regimen	Inhibits HIV protease	Check liver function tests. Check blood glucose. Instruct patients to take this drug with food. Monitor ECG. Assess for body shape changes.	The drug is liver toxic and can cause elevations in bilirubin. This drug can cause hyperglycemia. Food increases absorption of the drug. The drug can prolong PR interval. Fat redistribution is a common side effect of this drug.
Darunavir (Prezista) 600 mg twice daily if the patient has been on a HAART regimen, ritonavir 100 mg daily is needed to maximize the drug's effect. 800 mg of darunavir once daily is prescribed along with 100 mg of ritonavir once daily if the patient has not previously been taking a HAART regimen	Inhibits HIV protease	Check liver function tests. Check for skin rash. Nausea, vomiting, diarrhea, headache. Assess for body shape changes.	The drug is liver toxic and can cause elevations in transaminases. Skin rash is a common side effect of this drug and can be severe. These manifestations are common side effects of darunavir. Fat redistribution is a common side effect of this drug.
Fosamprenavir (Lexiva) 700 mg twice daily if the patient has been on a HAART regimen, ritonavir 100 mg daily is needed to maximize the drug's effect. 1400 mg twice daily if the patient has not previously been taking a HAART regimen	Inhibits HIV protease	Check liver function tests. Assess for body shape changes.	The drug is liver toxic and can cause elevations in transaminases. Fat redistribution is a common side effect of this drug.
Indinavir (Crixivan) 800 mg every 8 hours or 800 mg twice daily along with 100 mg of ritonavir twice daily	Inhibits HIV protease	Instruct the patient that this drug may be taken with or without food. Assess for body shape changes. Monitor for back pain, dysuria, hematuria. Check liver function tests. Instruct the patient that this drug may be taken with or without food. Check for nausea, vomiting, diarrhea. Check liver function tests. Check lipids. Assess for body shape changes. Instruct the patient to take this drug with food. Check for diarrhea. Check liver function tests. Check blood glucose. Assess for body shape changes.	Fewer dietary restrictions increase adherence to drug regimen. Fat redistribution is a common side effect of this drug. Kidney stones are common. The drug is liver toxic and can cause elevations in bilirubin. Fewer dietary restrictions increase adherence to drug regimen. These manifestations are common side effects of lopinavir. The drug is liver toxic and can cause elevations in transaminases and bilirubin. Elevated triglycerides common. Fat redistribution is a common side effect of this drug. Food increases tolerability and absorption. Diarrhea is a common side effect of this drug. The drug is liver toxic and can cause elevations in transaminases. This drug can elevate blood glucose levels. Fat redistribution is a common side effect of this drug.
Lopinavir/ritonavir (Kaletra) 200 mg/50 mg coformulated tablets 2 tablets twice daily	Inhibits HIV protease		
Nelfinavir (Viracept) 1250 mg twice daily or 750 mg three times daily	Inhibits HIV protease		

Continued

CHART 21-9 COMMON EXAMPLES OF DRUG THERAPY

HIV Infection—cont'd

DRUG/ USUAL DOSE (FOR ADULTS WEIGHING >60 kg)	PHYSIOLOGIC PURPOSE	NURSING INTERVENTIONS	RATIONALE
Saquinavir (Invirase) 1000 mg twice daily This drug requires co-administration with 100 mg of zidovudine to maximize drug effectiveness	Inhibits HIV protease	Instruct the patient to take this drug with food. Check for nausea, vomiting, diarrhea. Check liver function tests. Check lipids, glucose. Assess for body shape changes.	Food increases tolerability and absorption. Common side effects. The drug is liver toxic and can cause elevations in transaminases. Elevated cholesterol, glucose. Fat redistribution is a common side effect of this drug.
Tipranavir (Aptivus) 500 mg twice daily This drug requires co-administration with 100 mg of zidovudine to maximize drug effectiveness	Inhibits HIV protease	Instruct patients to take this drug with food. Check liver function tests. Check for skin rashes. Check lipids, glucose. Assess for body shape changes.	Food increases tolerability and drug absorption. The drug is liver toxic and can cause elevations in transaminases and other liver enzymes. Skin rash is a common side effect of this drug and can be severe. The drug can elevate cholesterol levels and glucose levels. Fat redistribution is a common side effect of this drug.
Integrase Inhibitors			
Raltegravir (Isentress) 400 mg twice daily	Inhibits HIV integrase	Instruct the patient that this drug may be taken with or without food.	Fewer dietary restrictions increase adherence to drug regimen.
Fusion Inhibitors			
Enfuvirtide (Fuzeon) 90 mg subcutaneously twice daily	Prevents cellular fusion between HIV and T-cell	Reconstitute with sterile water only, may be stored after reconstitution in refrigerator if used within 24 hours. Monitor skin for erythema, nodules at injection site.	Drug is less effective if not mixed and stored according to manufacturer's directions. Local injection reactions are common.
Entry Inhibitor/CCR5 Antagonist			
Maraviroc (Selzentry) 150 mg twice daily	Blocks CCR5 co-receptor	Monitor for cough, dizziness, rash, fever.	Common side effects.
Combination Products (Co-formulation of drugs decreases pill burden and increases drug adherence)			
Combivir (lamivudine 150 mg + zidovudine 300 mg) One tablet twice daily	Combination of two different NRTIs that generate bad nucleoside/nucleotide building blocks	Follow the same nursing interventions as for each drug alone.	Combination drugs have the same side effects as each drug individually.
Trizivir (lamivudine 150 mg + zidovudine 300 mg + abacavir 300 mg) One tablet once daily	Combination of three different NRTIs that generate bad nucleoside/nucleotide building blocks	Follow the same nursing interventions as for each drug alone.	Combination drugs have the same side effects as each drug individually.
Epzicom (lamivudine 300 mg + abacavir 600 mg) One tablet once daily	Combination of two different NRTIs that generate bad nucleoside/nucleotide building blocks	Follow the same nursing interventions as for each drug alone.	Combination drugs have the same side effects as each drug individually.
Truvada (emtricitabine 200 mg + tenofovir 300 mg) One tablet once daily	Combination of two different NRTIs that generate bad nucleoside/nucleotide building blocks	Follow the same nursing interventions as for each drug alone.	Combination drugs have the same side effects as each drug individually.
Atripla (emtricitabine 200 mg + tenofovir 300 mg + efavirenz 600 mg) One tablet once daily	Combination of two different NRTIs that generate bad nucleoside/nucleotide building blocks	Follow the same nursing interventions as for each drug alone.	Combination drugs have the same side effects as each drug individually.

CBC, Complete blood count; CNS, central nervous system; ECG, electrocardiogram; GFR, glomerular filtration rate.

needed to enter the cell. So, this class of drug prevents cellular infection with HIV. Because the drug specifically blocks only the *CCR5* receptor, testing with the *CCR5* Trofile Test is needed before drug therapy to determine whether a patient's viruses have this receptor. If it is not present and the virus uses the *CXCR4* receptor instead, the drug is ineffective at preventing HIV entry.

Integrase inhibitors are the newest type of anti-HIV drug. The major drug in this category is raltegravir (Isentress). It works to prevent infection by inhibiting the HIV enzyme—*integrase*, which the virus brought with it to insert the viral DNA into the host cell's human DNA. Without this action, viral proteins are not made and viral replication is inhibited.

As indicated in Chart 21-9, many HIV drugs are formulated as combination tablets and capsules, often having two or three HIV-active drugs in a single preparation. This practice reduces the number of individual drugs a patient must take daily, increases drug adherence, and helps ensure the patient is receiving the proper drug at the correct dosage.

Immune Enhancement. Research is being conducted to evaluate treatments that may enhance or replenish the immune system of patients with AIDS. Some of these methods include stem cell transplantation, lymphocyte transfusion, and infusions of lymphokines (particularly interleukin-2) and other biological response modifiers (especially white blood cell colony-stimulating factors and red blood cell growth factors).

CONSIDERATIONS FOR OLDER ADULTS

Metabolic differences associated with aging reduce drug deactivation and slow drug elimination in older adults. Retention of active drug can lead to a more rapid buildup to toxic levels and increase the likelihood of adverse effects of HAART drugs. Thus many older adults require dosage adjustments to reduce the risk for serious side effects. Complications of HAART among older adults include heart disease, kidney disease, liver disease, and other comorbidities that often require additional types of drug therapy (Vance, 2010).

Complementary and Alternative Therapies. Complementary therapies are often used by people with HIV/AIDS. Such therapies include vitamins, shark cartilage, and botanical products available at health food stores. The usefulness of these products has yet to be established through well-controlled clinical trials. In addition, some botanicals alter the effects of prescription drugs. Ask the patient which botanicals he or she is using, and check with the pharmacist to determine known drug interactions with HAART.

NCLEX EXAMINATION CHALLENGE

Health Promotion and Maintenance

The client who is prescribed highly active antiretroviral therapy (HAART) is flying to a wedding and will be gone 1 day. He asks if he can skip his drugs that day so that he doesn't have to show them all at the airport. What is the nurse's best response?

- "Yes, just 1 day off your drugs will not make any difference."
- "Yes, as long as you avoid direct contact with anyone who is ill."
- "No, even 1 day off the drugs can help the virus become drug resistant."
- "No, even 1 day off the drugs increases the chances that you can spread the disease."

Enhancing Oxygenation

Planning: Expected Outcomes. The patient is expected to maintain adequate oxygenation and perfusion and to have minimal dyspnea. Indicators include:

- Rate and depth of respiration within the normal range
- Pulse oximetry within the normal range
- Absence of cyanosis or pallor and abnormal breath sounds

Interventions. The nurse or respiratory therapist uses drug therapy, respiratory support and maintenance, comfort, and rest.

Drug therapy is a mainstay for gas exchange problems resulting from infection. Appropriate drug therapy is started after an infectious or other cause for respiratory difficulty is identified. A common respiratory infection among people with HIV disease or AIDS is *Pneumocystis jiroveci* pneumonia (PCP) (formerly known as *Pneumocystis carinii* pneumonia). The treatment of choice for PCP is trimethoprim/sulfamethoxazole (Apo-Sulfatrim, Bactrim, Cotrim, Septra). Many patients with AIDS have adverse reactions to this drug, including nausea, vomiting, hyponatremia, rashes, fever, leukopenia, thrombocytopenia, and hepatitis.

Pentamidine isethionate (Pentacarinat, Pentam), usually given IV or IM, is also used to treat PCP. Aerosolized pentamidine isethionate is used as prophylaxis for patients with CD4+ T-cell counts below 200, as well as for those who have already had PCP.

Other drug therapies include bronchodilators to improve airflow, as well as dapsone (Avlosulfon) and atovaquone (Mepron), which can be used as therapy for existing PCP or as prophylaxis. For moderate to severe PCP, steroids may be used to reduce the inflammation.

Respiratory support and maintenance are important to maintain respiratory function and avoid complications. Assess the respiratory rate, rhythm, and depth, breath sounds, and vital signs and monitor for cyanosis at least every 8 hours. Apply oxygen and humidify the room as prescribed. Also monitor mechanical ventilation, perform suctioning and chest physical therapy as needed, and evaluate blood gas results.

Comfort can help improve gas exchange. Assess the patient's comfort. The patient with difficulty breathing may be more comfortable with the head of the bed elevated. Pace activities to reduce shortness of breath and fatigue. Provide psychological support during periods of breathing difficulty.

Rest and activity changes are needed when gas exchange is impaired. Most patients with HIV/AIDS have fatigue, especially when respiratory problems also are present. Certain treatments worsen fatigue. Consult with the patient to pace activities to conserve energy. Guide the patient in active and

NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

Which activity is most appropriate for the nurse to eliminate or modify to prevent excessive fatigue in the client with reduced oxygenation as a result of respiratory infections and AIDS?

- Mouth care
- Meal times
- Complete bath
- Dressing changes

passive range-of-motion (ROM) exercises. Schedule non-time-critical activities, such as bathing, so that he or she is not fatigued at mealtime.

Managing Pain

The patient with severe HIV disease or AIDS often has pain from many causes. Pain can result from enlarged organs stretching the viscera or compressing nerves. Tumor invasion of bone and other tissues can cause pain, as can nerve compression from swollen lymph nodes. Many patients with AIDS have peripheral neuropathy-induced pain from the disease or drug therapies. Many have generalized joint and muscle pain.

Planning: Expected Outcomes. The patient is expected to achieve an acceptable level of comfort and pain reduction. Indicators include:

- Reporting that pain is controlled to a level that is acceptable to him or her
- Absence of indicators of acute pain (increased heart rate and blood pressure)
- Absence of facial grimacing, teeth clenching
- Willingness to move and participate in self-care

Interventions. Drug therapy and other approaches are used together to manage pain in the patient with HIV/AIDS, depending on the cause of the pain.

Comfort measures include the use of pressure-relieving mattress pads, warm baths or other forms of hydrotherapy, massage, and applying heat or cold to painful areas to help reduce pain levels, with or without drug therapy. Take care when moving or assisting the patient. Use lift sheets to avoid pulling or grasping the patient with joint pain. The patient may be thin and have poor circulation, contributing to pain and discomfort. Help him or her change positions often.

Drug therapy with different classes of drugs is used to manage pain from different causes. For arthralgia and myalgia, NSAIDs may reduce inflammation and increase comfort without inducing drowsiness. The controlled substance pregabalin (Lyrica) may provide some relief from muscle and joint pain. The neuropathic pain of peripheral neuropathy may respond best to tricyclic antidepressants such as amitriptyline (Elavil) or to anticonvulsant drugs such as gabapentin (Neurontin), phenytoin (Dilantin), or carbamazepine (Tegretol), although these drugs often interact with antiretroviral drugs. Drugs for neuropathic pain may take from several days to weeks before a full effect is seen. During this time, opioids may be needed to control pain.

When opioids are used, assess the patient for pain intensity and quality. Mild to moderate pain is treated with weaker opioids such as oxycodone or codeine. More intense pain is treated with stronger opioids such as morphine, hydromorphone (Dilaudid), or fentanyl transdermal (Duragesic). Combinations of weak and strong opioids along with non-opioid drugs may be used to provide the best sustained pain relief and allow the patient to participate in activities to the extent that he or she wishes.

Complementary and alternative therapies are used by many patients with pain from HIV/AIDS. These include guided imagery, distraction, progressive relaxation, body-talk, and biofeedback to help control pain. Such therapies can be used with more traditional and pharmacologic measures to improve comfort.

Enhancing Nutrition

Many patients with AIDS have difficulty maintaining their weight and nutritional status. This problem may be caused by fatigue, anorexia, nausea and vomiting, difficult or painful swallowing, diarrhea, intestinal malabsorption, or wasting syndrome.

Planning: Expected Outcomes. The patient is expected to maintain optimal weight through adequate nutrition and hydration. Indicators include:

- Selecting foods high in calories and protein
- Maintaining current weight or gaining weight
- Drinking at least 2 to 3 L of fluids per day
- Maintaining blood levels of ferritin, albumin, prealbumin, and hemoglobin within normal ranges

Interventions. Because there are many factors for poor nutrition in AIDS, diagnostic procedures are needed to determine the cause. Once the cause is determined, appropriate therapy is initiated. For example, in the patient who has candidal esophagitis, nutrition is affected because of swallowing difficulties.

Drug therapy can include ketoconazole (Nizoral) or fluconazole (Diflucan) orally, or IV amphotericin B (Fungizone). Administer the drug as prescribed, and monitor for side effects such as nausea and vomiting, which also affect nutrition. Provide mouth care and ice chips, and keep unpleasant odors out of the patient's environment. Antiemetics are used as needed.

Nutrition therapy includes monitoring weight, intake and output, and calorie count. Assess food preferences and any dietary cultural or religious practices. Teach the patient about a high-calorie, high-protein, nutritionally sound diet. Encourage him or her to avoid dietary fat, because fat intolerance often occurs as a result of the disease and as a side effect of some antiretroviral medications. Collaborate with the registered dietitian to provide an appropriate diet, including small, frequent meals (better tolerated than large meals). Supplemental vitamins and fluids are indicated in some cases. For the patient who cannot achieve adequate nutrition through food, tube feedings or total parenteral nutrition may be needed.

Mouth care performed frequently can improve appetite. When this nursing action is delegated to unlicensed assistive personnel (UAP), instruct them to offer the patient rinses of sodium bicarbonate with sterile water or normal saline every 2 hours or several times a day. Explain to UAP why the patient should use a soft toothbrush and the need to drink plenty of fluids. For oral pain, general analgesics or oral anesthetic gels and solutions may be needed.

Complementary and alternative therapies to promote healing of mouth sores can help improve nutritional intake. Some patients have found relief from oral thrush with the use of lemon juice and lemongrass infusions. This practice is more common in less affluent countries where antifungal drugs may not be available or the cost is prohibitive (Wright et al., 2009).

Minimizing Diarrhea

Patients with AIDS often suffer from diarrhea. Sometimes an infectious cause (e.g., *Giardia*, *Cryptosporidium* or amoeba) can be determined and treated, or the cause is determined but no effective therapy is available. Many patients are lactose intolerant, and HIV disease worsens the condition. Diarrhea may occur as a side effect of therapy with protease inhibitors.

In some cases, patients with AIDS have diarrhea and no cause can be identified.

Planning: Expected Outcomes. The patient is expected to have decreased diarrhea; to maintain fluid, electrolyte, and nutritional status; and to reduce incontinence. Indicators include:

- Has a stool amount that is appropriate for the diet
- Expels stools that are formed and soft
- Recognizes urge to defecate
- Maintains control of stool passage

Interventions. For most patients with AIDS and diarrhea, symptom management is all that is available. Antidiarrheals, such as diphenoxylate hydrochloride (Diarsed , Lomotil) or loperamide (Imodium), given on a regular schedule, provide some relief. Consult with the dietitian and offer dietary counseling about appropriate foods. Recommended dietary changes include less roughage; less fatty, spicy, and sweet food; and no alcohol or caffeine. Some patients obtain relief when they eliminate dairy products from the diet or eat smaller amounts of food more often and drink plenty of fluids, especially between meals.

Assess the perineal skin of the patient with diarrhea every 8 to 12 hours for a change in skin integrity. Provide him or her with a bedside commode or a bedpan if needed. Some patients cannot reach the bathroom in time because of immobility or anal sphincter weakness and others because of the urgency to defecate. Teach UAP performing this care to provide the patient with privacy, support, and understanding. Explain the need to keep the patient's perineal area clean and dry. Instruct UAP to report any skin changes in the perineal area, including persistent redness, rashes, blisters, or open areas. Collaborate with a wound care specialist for more interventions to manage anal excoriation and discomfort.

NCLEX EXAMINATION CHALLENGE

Health Promotion and Maintenance

Which snack choice does the nurse recommend to the client with AIDS to help improve nutritional status?

- A. An ice cream sandwich
- B. Two soft-cooked eggs
- C. A wand of cotton candy
- D. A serving of French fried potatoes

Restoring Skin Integrity
